WILEY ENGINEERING
HANDBOOK SERIES

NEW YORK : JOHN WILEY & SONS, INC.
LONDON : CHAPMAN & HALL, LIMITED

PUBLISHER'S PREFACE

In making plans for new editions of our handbooks in mechanical engineering and in electrical engineering, it soon became clear that engineering science and practice had developed to such an extent that handbooks were growing beyond all practical bounds. They had become both bulky and inconvenient and contained much duplicated material. In order to solve the problems presented by these conditions, the editors of our various handbooks were asked to serve as an advisory editorial board.

This board recommended, first, that the fundamental material underlying all engineering be published in a separate volume, and, second, that the existing handbooks as they are revised be issued in several volumes containing material closely related to the specialized branches of engineering. As a result of these recommendations, the Wiley Engineering Handbook Series has been initiated, which in the beginning will comprise the following: Eshbach's "Handbook of Engineering Fundamentals"; Kent's "Mechanical Engineers' Handbook" in two volumes, viz., "Power" and "Design and Shop Practice"; Pender's "Electrical Engineers' Handbook" in two volumes, viz., "Electric Power" and "Communication and Electronics."

This division has also made it possible to devote more space to the various topics so that the entire new series of handbooks contains more complete information on all topics than heretofore has been possible. It is our hope that this new plan will give engineers information that is more useful, more complete, and in more convenient form.

JOHN WILEY & SONS, INC.

PREFACE TO THE ELEVENTH EDITION,

July 1936.

In the preparation of the eleventh edition of this book, the principle that has governed the ten previous editions has constantly been kept in mind—namely, that it must represent the *practice* of mechanical engineering. The changes that have taken place in engineering in the 13 years that have elapsed since the 10th edition was published have been many and great. To conform to these changes, a complete rewriting of the book has been necessary.

Advantage has been taken of this to change the arrangement, form and typography, to make a book that would better fill its field and be more usable. The larger page permits the use of larger type and illustrations. The separation of the book into volumes, each covering more or less closely related subjects, makes it more convenient for the engineer interested in only a limited field.

A further radical change is the inclusion in a separate volume under the editorship of O. W. Eshbach of the discussion of the fundamental sciences that underlie all engineering, thus permitting more space to be given to the practice in the other volumes.

It is believed that these changes will meet with the approval of the engineering profession, and that the book will continue to render the high degree of service that has characterized it for the past 42 years.

The editor-in-chief expresses his thanks to the collaborators whose co-operation has rendered this work possible. He also desires to thank Dr. Charles E. Lucke for many helpful suggestions. Thanks also are due to the many industrial organizations whose criticism and compilation of data have been of material assistance.

Robert Thurston Kent.

ABSTRACT FROM PREFACE TO THE FIRST EDITION, 1895.

More than twenty years ago the author began to follow the advice given by Nystrom: "Every engineer should make his own pocket-book, as he proceeds in study and practice, to suit his particular business." The manuscript pocket-book thus begun, however, soon gave place to more modern means for disposing of the accumulation of engineering facts and figures, viz., the index rerum, the scrap-book, the collection of indexed envelopes, portfolios and boxes, the card catalogue, etc. Four years ago, at the request of the publishers, the labor was begun of selecting from this accumulated mass such matter as pertained to mechanical engineering, and of condensing, digesting, and arranging it in form for publication. In addition to this, a careful examination was made of the transactions of engineering societies, and of the most important recent works on mechanical engineering in order to fill gaps that might be left in the original collection, and insure that no important facts had been overlooked.

Some ideas have been kept in mind during the preparation of the Pocket-book that will, it is believed, cause it to differ from other works of its class. In the first place it was considered that the field of mechanical engineering was so great, and the literature of the subject so vast, that as little space as possible should be given to subjects which especially belong to civil engineering.

Another idea prominently kept in view by the author has been that he would not assume the position of an "authority" in giving rules and formulæ for designing, but only that of compiler, giving not only the name of the originator of the rule, where it was known, but also the volume and page from which it was taken, so that its derivation may be traced when desired. When different formulæ for the same problem have been found they have been given in contrast, and in many cases examples have been calculated by each to show the difference between them. In some cases these differences are quite remarkable. Occasionally the study of these differences has led to the author's devising a new formula, in which case the derivation of the formula is given.

Much attention has been paid to the abstracting of data of experiments from recent periodical literature, and numerous references to other data are given. In this respect the present work will be found to differ from other Pocket-books.

William Kent.

TABLE OF CONTENTS

Alphabetical index follows Section 17

SECTION 1—AIR

SECTION 2—WATER

SECTION 3—HEAT

This book is divided into sections, each section carrying its independent sequence of page numbers. For example, 3-15 indicates Section 3, page 15.

TABLE OF CONTENTS

SECTION 4—COMBUSTION AND FUELS

SECTION 5—STEAM

SECTION 6—THE STEAM BOILER

SECTION 7—THE STEAM ENGINE

TABLE OF CONTENTS

SECTION 8—THE STEAM TURBINE

SECTION 9—CONDENSING AND COOLING EQUIPMENT

SECTION 10—REFRIGERATION AND ICE MAKING

SECTION 11—HEATING, VENTILATING AND AIR CONDITIONING

SECTION 12—INTERNAL COMBUSTION ENGINES

Diesel Engines

Gas Engines

Gasoline Engines

SECTION 13—GAS PRODUCERS

TABLE OF CONTENTS

SECTION 14—TRANSPORTATION

SECTION 15—ELECTRIC POWER

SECTION 16—POWER TEST CODES

SECTION 17—MATHEMATICAL TABLES

For Contents of other handbooks of this series see pages following Index of this Volume.

AIR

COMPRESSED AIR

By Robert Peele

FANS AND BLOWERS

By Robert Thurston Kent

TABLE OF CONTENTS

AIR

1. PROPERTIES OF AIR

Air is a mechanical mixture of the gases oxygen and nitrogen, with about 1% by volume of argon. Atmospheric air of ordinary purity contains about 0.04% of carbon dioxide. The composition of air according to various authorities is given in Table 1.

Table 1.—Composition of Air, According to Various Authorities

	By Volume			By Weight		
	N	O	Ar	N	O	Ar
1	79.3	20.7	....	77	23	....
2	79.09	20.91	....	76.85	23.15	....
3	78.122	20.941	0.937	75.539	23.024	1.437
4	78.06	21	0.94	75.5	23.2	1.3

(1) Values formerly given in books on physics. (2) Average results of several determinations, Hempel's Gas Analysis. (3) Sir Wm. Ramsay, *Bull. U. S. Geol. Survey*, No. 330. (4) A. Leduc, *Comptes Rendus*, 1896, *Jour. Franklin Inst.*, Jan., 1898. Leduc gives for the density of oxygen relatively to air 1.10523; for nitrogen 0.9671; for argon, 1.376.

The weight of pure air at 32° F. and a barometric pressure of 29.92 in. of mercury, or 14.6963 lb. per sq. in., or 2116.3 lb. per sq. ft., = 0.080728 lb. per cu. ft.; volume of 1 lb. = 12.387 cu. ft. At any other temperature and barometric pressure its weight in lb. per cubic foot is $W = \frac{1.3253 \times B}{459.6 + T}$, where B = height of the barometer, T = temperature, deg., F. and 1.3253 = weight in lb. of 459.6 cu. ft. of air at 0° F. and 1 in. barometric pressure. Air expands 1/494.6 of its volume at 32° F. for every increase of 1° F., and its volume varies inversely as the pressure.

Table 2.—Conversion Table for Air Pressures

	Lb. per sq. ft.	In. of Water	Oz. per sq. in.	Ft. of Water	In. of Mercury	Lb. per	Ft. of Air at 62° F.*	$V = \sqrt{2g}$ ft. per sec.†

* The figures in this column show the head in feet of air of uniform density at atmospheric pressure and 62° F. corresponding to the pressure in the preceding columns.

† The figures in this column show the theoretical velocities corresponding to these heads, or the velocities of a jet flowing from a frictionless conical orifice whose flow coefficient is unity.

THE AIR-MANOMETER consists of a long, vertical glass tube, closed at the upper end, open at the lower end, containing air, provided with a scale. It is immersed, together with a thermometer, in a transparent liquid, such as water or oil, contained in a strong glass cylinder which communicates with the vessel in which the pressure is to be ascertained. The scale shows the volume occupied by the air in the tube.

Let v_0 = volume, at 32° F., p_0 = the mean pressure of the atmosphere, v_1 = volume of the air at the temperature t, and under the absolute pressure to be measured p_1; then

$$p_1 = \{(t + 459.6)\ p_0\, v_0\} \div (491.6\, v_1).$$

ATMOSPHERIC PRESSURE AT DIFFERENT ALTITUDES.—The pressure of the atmosphere in lb. per sq. in. at any altitude may be closely approximated for ordinary temperatures by multiplying the height of the mercury barometer, in inches, by 0.491. The pressure increases with the depth below the earth's surface, and is equal to about 1 in. rise in the barometer for each 900 ft. of depth. This is an approximate rule for ascertaining the depth of mine shafts. See Fig. 1.

LEVELING BY BAROMETER.—Many conditions combine to render the results of barometric leveling unreliable where accuracy is required. It is difficult to read an

aneroid (the barometer commonly used by engineers) to within, say, 2 to 6 ft., depending on its size. The results are affected by moisture or dryness of the air, winds, vicinity of mountains, and the daily atmospheric tides, all causing barometric fluctuations. A barometer hanging quietly in a room may vary 0.1 in. within a few hours, corresponding to nearly 100 ft. difference in elevation. No formula can embrace these sources of error.

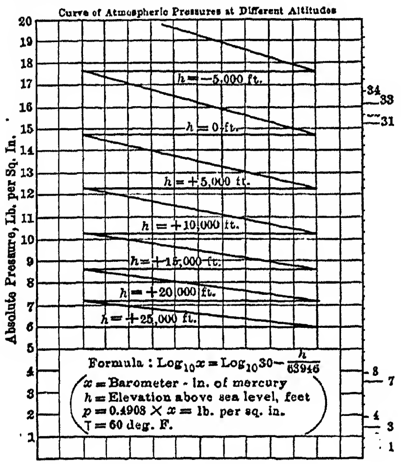

Fig. 1. Variation of Pressure with Altitude

LEVELING BY BOILING POINT OF WATER.—Tables 3 and 4 with explanation below are sufficiently accurate for many purposes.

Take from Table 4 the altitudes opposite the respective boiling temperatures, or the barometer readings. Subtract the one opposite the lower reading from that opposite the higher reading. The remainder will be the approximate required height. To correct this, add together the two thermometer readings, and divide by 2, for their mean. From table of temperature corrections take the number under this mean. Multiply by this number the approximate height just found.

At 70° F. pure water will boil at 1° lower temperature for an average of about 550 ft. of elevation above sea level, up to a height of ½ mile. At a height of 1 mile, 1° boiling temperature will correspond to about 560 ft. of elevation. In the table the mean of the temperatures at the two stations is assumed to be 32° F., at which no correction for temperature is necessary.

MOISTURE IN THE ATMOSPHERE.—Atmospheric air always contains a small quantity of carbon dioxide (see Ventilation), and a varying quantity of aqueous vapor or moisture. The relative humidity of the air at any time is the percentage of moisture

contained in it, as compared with the amount it is capable of holding at the same temperature.

The degree of saturation or relative humidity of the air is determined by the use of the dry and wet bulb thermometer. The degree of saturation for a number of different readings of the thermometer is given in Table 9, condensed from the Hygrometric Tables of the U. S. Weather Bureau.

Below 32° F. the pressure of saturated vapor in contact with ice is given. Values in the last column do not include the heat of the liquid. Below 32° F. the heat of sublimation of ice instead of the latent heat of vaporization is used.

MOISTURE IN AIR AT DIFFERENT PRESSURES AND TEMPERATURES.—(Saunders and Hirschberg.)—When air is termed dry or wet, it means only that it is dryer or wetter than air elsewhere. An important function of the atmosphere is the conveyance and distribution of water over the earth. Examples of mean percentages of atmospheric humidity are (Tables U. S. Weather Bureau): Galveston, 85; New York, 73; Walla Walla, Wash., 65; Rapid City, S. D., 60; Salt Lake City, 63; Yuma, Ariz., 42; El Paso, Tex., 39.

Moisture intermixed with air is in the form of transparent and invisible vapor, until a humidity of 100% or the point of saturation (dew point) is reached. This always occurs in the compression and transmission of air at ordinary working pressures, say, 75 lb. per sq. in. gage. When this point is passed, the excess moisture, though still mixed with the air, condenses into actual water. The supersaturated air then appears as fog or mist. In quiescent air the freed water slowly precipitates.

The varying point of saturation of air is determined by its pressure and temperature, especially the latter. At a fixed temperature, a given volume of air is saturated when it contains a certain quantity of water vapor. If the absolute pressure is doubled, reducing the volume one-half, the moisture capacity is reduced in the same proportion; so if the humidity of the free air is 50%, it becomes 100% when the air is compressed to 2 atmospheres or to 15 lb. per sq. in. gage, and if it is compressed to 6 atmospheres or 75 lb. per sq. in. gage, a common working pressure, the humidity becomes 300%, the excess over 100% being deposited. This is the case if the temperature remains constant. But as air is compressed, its temperature rises rapidly, and with each rise of 20° F. its capacity for moisture is doubled. If free air at 60° F. is compressed to 75 lb. per sq. in. gage, its temperature at delivery, however perfectly the compressor cylinder be water-jacketed, will be above 300° F. Due to this increase of temperature, the capacity of air for moisture will have been doubled so many times that, when it leaves the cylinder, the relative humidity of the air will be quite low, although all the original moisture is still present.

The conditions under which the compressed air has the lowest capacity for moisture are high pressure and low temperature. The temperature of the air leaving the compressor is reduced in its flow through the pipes, so that at the point where its work is to be done, the air should be at a low temperature and carry a minimum of moisture, if the condensed moisture has been removed.

To determine what percentage of moisture pure air can contain at various pressures and temperatures, to ascertain how low the "relative humidity" of the atmosphere must be to prevent deposition of water in any part of a compressed-air system and to find to what temperature air drawn from a saturated atmosphere must be cooled to cause

the deposition of moisture to begin, the following formulas and tables (by H. M. Murphy, *Eng. News*, June 18, 1908) are used, based on Dalton's law of gaseous pressures.

Dalton's Law.—The total pressure exerted against the interior of a vessel by a given quantity of a mixed gas enclosed in it is the sum of the pressures which each of the component gases would exert separately if it were enclosed alone in a vessel of the same volume and at the same temperature.

Table 10.—Mixtures of Air and Saturated Vapor
(From Goodenough's Tables)

FORMULAS FOR WEIGHT OF AIR, STEAM AND SATURATED VAPOR.—(Copyright, 1908, by H. M. Prevost Murphy.) Formulas for the weight of 1 cu. ft. of dry air, of 1 cu. ft. of saturated steam or water vapor and the maximum weight of water vapor that 1 lb. of pure air can carry at any pressure and temperature are given below.

The values K and H being given in Table 11 for various temperatures, t, the formulas are:

$$\text{Weight of 1 cu. ft. saturated steam} = 1.325271\,KH/(459.2 + t). \qquad [1]$$

H = elastic force or tension of water vapor or saturated steam, in inches of mercury corresponding to the temperature t (Fahr.) = 2.036 × (gage pressure + atmospheric pressure, in pounds per square inch). K = the ratio of the weight of a volume of saturated steam to an equal volume of pure dry air at the same temperature and pressure, $= 0.6113 + [0.092\,t/(850 - t)]$. Values of K and H corresponding to the various temperatures t are given in Table 11.

$$\text{Weight of 1 cu. ft. pure dry air} = \frac{1.325271M}{459.2 + t} = \frac{2.698102P}{459.2 + t}. \qquad [2]$$

M = absolute pressure, in. of mercury. P = absolute pressure, lb. per sq. in. W = maximum weight, in lb., of water vapor, that 1 lb. of pure air can contain, when the temperature of the mixture is t, and the total or observed, absolute pressure in pounds per square inch is $P = KH/(2.036\,P - H)$.

NOTE.—The results obtained by the use of any of the above formulas agree exactly

with the average data for air and steam weights as given by the most reliable authorities and careful experiments, for all pressures and temperatures; the value of K being correct for all temperatures up to the critical steam temperature of 689° F.

Table 11.—Values of K and H Corresponding to Temperatures from −30° to 434° F.

Application of the Formulas and Tables. Example 1.—What must be the relative humidity when atmospheric pressure is 14.7 lb. per sq. in. and outside temperature is 60° F., if no moisture is to be deposited in any part of a compressed air system carrying a constant gage pressure of 90 lb. per sq. in.? *Ans.*—The maximum weight of moisture that 1 lb. of pure air can contain at 90 lb. gage, (= 104.7 lb. absolute pressure) and 60° F., is

$$W = \frac{KH}{2.036P - H} = \frac{0.6183 \times 0.5180}{} = 0.001506 \text{ lb.}$$

The maximum weight of moisture that 1 lb. of air can contain at 60° F. and 14.7 lb. (absolute pressure) is

$$W \text{ (at 14.7)} = \frac{0.6183 \times 0.5180}{2.036 \times 14.7 - 0.5180} = 0.01089 \text{ lb.}$$

In order that no moisture may be deposited, the relative humidity must not be above

$$(0.001506 \div 0.01089) \times 100 = 13.83\%.$$

Example 2.—When compressing air into a reservoir carrying a constant gage pressure of 75 lb., from a saturated atmosphere of 14.7 lb. absolute pressure and 70° F., to what temperature must

the air be cooled after compression to cause the deposition of moisture to begin? *Ans.*—First find the maximum weight of moisture contained in 1 lb. of pure air at 14.7 lb. pressure and 70° F.

$$W = \frac{KH}{2.036\,P - H} = \frac{0.6196 \times 0.7332}{2.036 \times 14.7 - 0.7332} = 0.01556 \text{ lb.}$$

The temperature to which the air must be cooled to cause the deposition of moisture may be found by placing 0.01556, together with P equal to 75 + 14.7 in the equation thus:

$$0.01556 = \frac{KH}{2.036 \times 89.7 - H} = \frac{KH}{182.63 - H},$$

or $H = 2.842/(0.01556 + K)$, and the temperature which satisfies this equation is found by aid of the table (by trial and error) to be approximately 129° F.

Example 3.—When the outside temperature is 82° F., and the pressure of the atmosphere is 14.6963 lb. per sq. in., the relative humidity being 100%, how many cu. ft. of free air must be compressed and delivered into a reservoir at 100 lb. gage to cause 1 lb. of water to be deposited when the air is cooled to 82° F.? *Ans.*—Weight of moisture mixed with 1 lb. of air at 82° F., and atmospheric pressure = 0.023526 lb. For 100 lb. gage pressure,

$$W = \frac{KH}{2.036\,P - H} = \frac{0.6211 \times 1.092}{2.036 \times 114.6963 - 1.092} = 0.002918 \text{ lb.}$$

Weight of moisture deposited by each pound of compressed air is equal to 0.023526 − 0.002918 = 0.020608 lb. Each cubic foot of the moist atmosphere contains 0.070595 lb. of pure air. Therefore the number of cubic feet of air that must be delivered to cause 1 lb. of water to be deposited is

$$(1/0.070595) \times (1/0.020608) = 687.37 \text{ cu. ft.}$$

Example 4.—Under the same conditions as in Example 3, what is the loss in volumetric efficiency of the plant when the excess moisture is properly trapped in the main reservoirs? *Ans.*—Before compression, each pound of air is mixed with 0.023526 lb. of water vapor and the weight of 1 cu. ft. of the mixture is 0.072256 lb. Hence the volume of the mixture is

$$1.023526 \div 0.072256 = 14.165 \text{ cu. ft.}$$

For 100 lb. gage pressure and 82° F. as in Example 3, 1 lb. of air can hold 0.002918 lb. of in suspension, having deposited 0.020608 lb. in the reservoir. The weight of 1 cu. ft. of

Table 12.—Weights of Pure Dry Air, Water Vapor and Saturated Mixtures of Air , Water Vapor, and Pressure of Air and Vapor Present in Saturated Mixtures

Air at atmospheric pressure = 14.6963 lb. per sq. in. = 29.921 in. of mercury, and at various temperatures.

vapor at 82° is 0.001661 lb.; consequently by Dalton's law the volume of the mixture of 1 lb. of air and 0.002918 lb. of water vapor at 100 lb. gage pressure is the same as that of the vapor or saturated steam alone; that is, $0.002918 \div 0.001661 = 1.757$ cu. ft.

By Mariotte's law, the volume of the 1.757 cu. ft. of mixed gas at 114.6963 lb., absolute, when expanded to atmospheric pressure will be

$$(114.6963 \div 14.6963) \times 1.757 = 13.712 \text{ cu. ft.};$$

hence the decrease of volume, or the loss of volumetric efficiency, is

$$14.165 - 13.712 = 0.453 \text{ cu. ft., or } (0.453 \div 14.165) \times 100 = 3.2\%.$$

This shows that in warm, moist climates, there is an appreciable loss in the efficiency of compressors, due to the condensation of water vapor.

SPECIFIC HEAT OF AIR AT CONSTANT VOLUME AND AT CONSTANT PRESSURE.—Volume of 1 lb. of air at 32° F. and pressure of 14.7 lb. per sq. in. = 12.387 cu. ft. = a column 1 sq. ft. area × 12.387 ft. high. Raising the temperature 1° F. while maintaining atmospheric pressure expands it $^1/_{492}$, or to 12.4122 ft. high, a rise of 0.02522 ft.

Work done = 2116 lb. per sq. ft. × 0.02522 = 53.37 ft.-lb., or $53.37 \div 778 = 0.0686$ heat units.

The specific heat of air at constant pressure C_p, according to Regnault, is 0.2375 B.t.u., but this includes the work of expansion, or 0.0686 B.t.u.; hence the specific heat at constant volume $C_v = 0.2375 - 0.0686 = 0.1689$ B.t.u.

Ratio of specific heat at constant pressure to specific heat at constant volume = $0.2375 \div 0.1689 = 1.406$. (See Specific Heat, p. 3–19.)

2. FLOW OF AIR

FLOW OF AIR THROUGH ORIFICES.—The theoretical velocity of flow in feet per second of any fluid, liquid, or gas through an orifice is $v = \sqrt{2gh} = 8.02\sqrt{h}$, in which h = the "head" or height of the fluid in feet required to produce the pressure of the fluid at the level of the orifice. (For gases the formula holds good only for small differences of pressure on the two sides of the orifice.) The quantity of flow in cubic feet per second is equal to the product of this velocity by the area of the orifice, in square feet, multiplied by a "coefficient of flow," which takes into account the contraction of the vein or flowing stream, the friction of the orifice, etc.

For air flowing through an orifice or short tube, from a reservoir of the pressure p_1 into a reservoir of the pressure p_2, Weisbach gives the following values for the coefficient of flow obtained from his experiments:

Flow of Air Through an Orifice

Coefficient c in formula $v = c\sqrt{2gh}$.

Diam. 1 cm. = 0.394 in.:						
Ratio of pressures	1.05	1.09	1.43	1.65	1.89	2.15
Coefficient	0.555	0.589	0.692	0.724	0.754	0.788
Diam. 2.14 cm. = 0.843 in.:						
Ratio of pressures	1.05	1.09	1.36	1.67	2.01	.....
Coefficient	0.558	0.573	0.634	0.678	0.723	.....

Flow of Air Through a Short Tube

Diam. 1 cm. = 0.394 in., length 3 cm. = 1.181 in.:						
Ratio of pressures $p_1 \div p_2$	1.05	1.10	1.30	.....	.....	.....
Coefficient	0.730	0.771	0.830	.....	.....	.....
Diam. 1.414 cm. = 0.557 in., length 4.242 cm. = 1.670 in.:						
Ratio of pressures	1.41	1.69	.....	.....	.....	.....
Coefficient	0.813	0.822	.....	.....	.....	.....
Diam. 1 cm. = 0.394 in., length 1.6 cm. = 0.630 in. Orifice rounded:						
Ratio of pressures	1.24	1.38	1.59	1.85	2.14	.....
Coefficient	0.979	0.986	0.965	0.971	0.978	.....

Clark (Rules, Tables, and Data, p. 891) gives, for the velocity of flow of air through an orifice due to small differences of pressure.

$$\frac{t-32}{493}$$

or simplified $$V = 352C\sqrt{\left[1 + 0.00203(t - 32)\right]\frac{h}{p}}, \quad \text{[4]}$$

in which V = velocity, ft. per sec.; $2g = 64.4$; h = height of the column of water, in.,

measuring the difference of pressure; t = the temperature, deg. F., and p = pressure, in. of mercury. 773.2 is the volume of air at 32° under a pressure of 29.92 in. of mercury when that of an equal weight of water is taken as 1.

For 62° F., the formula becomes $V = 363C\sqrt{h \div p}$, and if p = 29.92 in., $V = 66.35C\sqrt{h}$.

The coefficient of efflux C, according to Weisbach, is:

For conoidal mouthpiece, of form of the contracted vein, with pressures of from 0.23 to 1.1 atmospheres	C = 0.97 to 0.99
Circular orifices in thin plates	C = 0.56 to 0.79
Short cylindrical mouthpieces	C = 0.81 to 0.84
The same rounded at the inner end	C = 0.92 to 0.93
Conical converging mouthpieces	C = 0.90 to 0.99

The consideration of the adiabatic flow of a perfect gas through a frictionless orifice leads to the equation (R. J. Durley, *Trans.* A. S. M. E., xxvii, 193, 1906),

$$\ldots \, {}^{(\gamma+1)/\gamma} \Big] \quad [5]$$

where W = weight of gas discharged per second, lb.; A = area of cross-section of jet, sq. ft.; P_1 = pressure inside orifice, lb. per sq. ft.; P_2 = pressure outside orifice; V_1 = specific volume of gas inside orifice, cu. ft. per lb.; γ = ratio of specific heat at constant pressure to that at constant volume.

For air, where $\gamma = 1.404$, we have for a circular orifice of diameter d inches, the initial temperature of the air being 60° F. (or 521° abs.),

$$W = 0.000491d^2P_1 \qquad [6]$$

In practice the flow is neither frictionless, nor perfectly adiabatic, and the amount of heat entering or leaving the gas is not known. Hence the weight actually discharged is to be found from the formulas by introducing a coefficient of discharge (generally less than unity) depending on the conditions of the experiment and on the form of orifice employed.

Neglecting the changes of density and temperature occurring as the air passes through the orifice, a simpler, though approximate, formula for the ideal discharge is obtained:

$$W = 0.01369\, d^2 \sqrt{iP/T}. \qquad [7]$$

in which d = diameter, in., i = difference of pressures, in. of water, P = mean absolute

	.598	.596	.594	.593	

pressure in lb. per sq. ft., and T = absolute temperature, = degrees F. + 461. In the usual case, in which the discharge takes place into the atmosphere, P is approximately 2117 lb. per sq. ft., and

$$W = 0.6299\, d^2 \sqrt{i/T} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [8]$$

To obtain the actual discharge the values found by the formula are to be multiplied by an experimental coefficient C, values of which are given in Table 14.

Up to a pressure of about 20 in. of water (or 0.722 lb. per sq. in.) above the atmospheric pressure, the results of formulas [6] and [8] agree closely. At higher differences of pressure, divergence becomes noticeable. The formulas hold good only for orifices of the particular form experimented with, and bored in plates of the same thickness, viz.: iron plates 0.057 in. thick.

The experiments and curves plotted from them indicate that:—

(1) The coefficient for small orifices increases as the head increases, but at a lesser rate for the larger orifices, till for the 2-in. orifice it is almost constant. For orifices larger than 2 in. it decreases as the head increases, and at a greater rate the larger the orifice.

(2) The coefficient decreases as the diameter of the orifice increases, and at a greater rate the higher the head.

(3) The coefficient does not change appreciably with temperature (between 40° and 100° F.).

(4) The coefficient (at heads under 6 in.) is not appreciably affected by the size of the box in which the orifice is placed if the ratio of the areas of the box and orifice is at least 20 : 1.

FLIEGNER'S EQUATION FOR FLOW OF AIR THROUGH AN ORIFICE.— (Peabody's Thermodynamics, also *Trans.* A. S. M. E., xxvii, 194.)

$$W = 0.53A(P/\sqrt{T}). \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [9]$$

W = flow, lb. per second; A = area of the orifice (or sum of the areas of all the orifices), sq. in.; P = absolute pressure in the orifice chamber, lb. per sq. in.; T = absolute temperature, deg. F., of the air in the chamber. The formula applies only when the absolute pressure in the reservoir is greater than twice the atmospheric pressure, and for orifices properly made. The orifices are in hardened steel plates $^3/_8$ in. to $^1/_2$ in. thick, accurately ground, with the inside orifice rounded to a radius $^1/_{16}$ in. less than the thickness of the plate, leaving $^1/_{16}$ in. of the hole straight.

MEASUREMENT OF AIR BY LOW-PRESSURE NOZZLE TEST. (Compressed Air Society.)—Air from the compressor first passes into the regular receiver, where the pressure is maintained at the rated point by bleeding the air through a globe valve to a second receiver provided with a nozzle. This nozzle is an orifice to atmosphere, with curved inner edges. Its size is such that the pressure in the second receiver will not exceed 1 lb. per sq. in. above the atmosphere, when passing all the air through its opening. The pressure is shown by a water column. A thermometer in the wall of the second receiver, about 2 ft. back of the nozzle, measures the temperature of the flowing air. From temperature, pressure and barometric readings, the volume of air flowing per minute is determined.

Usually, the air at the nozzle is at from 150° to 250° F. The volumetric efficiency of the compressor is obtained by correcting the cubic feet of hot nozzle air to the equivalent volume at the temperature of the compressor intake.

Fig. 2 shows the apparatus. The diameter of receiver B must be at least 2 $^1/_2$ times

the smallest diameter of nozzle throat, preferably larger, and should be 10 to 15 ft. long. The revolutions of the compressor are recorded by a continuously operating counter, readings being taken to the second, every 3 or 4 minutes. When the nozzle is of such size that the water column reading is between 3 and 18 in., the quantity of air is calculated from the formula $V = \sqrt{2gh}$, where V = velocity, ft. per sec., g = acceleration due to

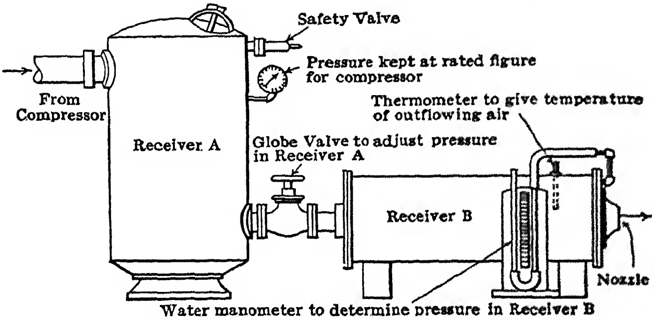

FIG. 2. Apparatus for Low-pressure Nozzle Test

gravity (32.2 usually) ft. per sec. per sec., and h = height, ft., of a column of air of uniform density, corresponding to the observed pressure causing the flow through the nozzle.

Observing the relations of pressure, volume and temperature and the specific weights of air and water, the following formula is derived:

$$Q = 3.64\ Kd^2 \sqrt{(HT \div P_m)} \qquad [10]$$

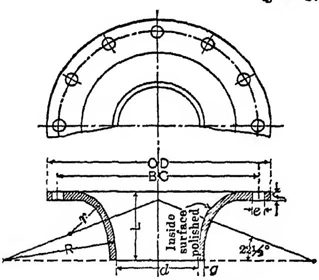

FIG. 3. Standard Nozzle

where Q = cu. ft. of air flowing per min. at the observed temperature of the *upstream side* of nozzle, and the absolute pressure of the *downstream* side (the latter is usually atmospheric pressure); d = diameter of smallest part of nozzle throat, in.; H = observed water column, in.; T = absolute temperature of air entering nozzle = observed temperature, deg. F., plus 460°; P_m = absolute mean pressure between entering and leaving sides of nozzle, lb. per sq. in.; K = coefficient of the nozzle, its value depending upon its shape. With accurately rounded edges, K is between 0.98 and 0.99. Table 16 gives the dimensions of standard nozzles, the inner surfaces of which must be polished and of the form shown by Fig. 3. Another, and more recent, form of nozzle, designed to measure the flow of air in fan and exhauster tests is shown on p. 16–67.

Instead of the above type of nozzle, H. B. Reynolds (*Trans.* A. S. M. E., xxxviii, 1916)

Table 16.—Dimensions of Standard Nozzles

has proposed the use of plain square orifices in a thin plate, as being easier to make than holes with mathematically rounded and polished edges. The following formula is then applied.

$$Q = \{405A(P_1^2 - P_2^2)^{0.48}\}/\sqrt{T} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [11]$$

where Q = cu. ft. of air discharged per min., at 32° F. and 14.7 lb. per sq. in., absolute; A = area of orifice, sq. in.; P_1 and P_2 = initial and final pressures, respectively, before and after this orifice, lb. per sq. in., absolute; T = absolute temperature of air entering the orifice, deg. F.

This formula, which gives quite satisfactory results, indicates that, for a stated flow, the area of orifice as computed by formula [9] for round orifices is about 20% too small. Fliegner's formula has sometimes been incorrectly used for square orifices, but is not applicable thereto.

Table 17.—Discharge of Air Through an Orifice

Flowing from a Receiver into the Atmosphere, through a Round Hole with Rounded Inner Edges

3. FLOW OF AIR IN PIPES

GENERAL FORMULAS.—In the flow of a liquid or gas, without friction, according to Bernoulli's theorem, $(V^2 \div 2g) + (p \div w) + z$ = a constant, where V = velocity, ft. per sec.; $2g$ = 64.35; p = absolute pressure, lb. per sq. ft.; w = density, lb. per cu. ft.; and z = height of the section of pipe above a given datum level. When the pipe is level, its axis is taken as datum, and z = 0.

When "fluid friction," or "skin friction" is taken into account there is a "loss of head" or "friction head" between any two selected points, such as the two ends of the pipe; that is, $H = fLv^2 \div R\,2g$; or $H = 4f\dfrac{L}{D}\dfrac{v^2}{2g}$; where H is the loss of head, or head causing the flow, measured in feet, of the fluid; f is a coefficient of friction, and R the mean hydraulic radius, which in circular pipes = 1/4 D. L is the length of the pipe and D the diameter, both in feet. By transposition the velocity in feet per second is

$$[illegible] \sqrt{\frac{[illegible]}{fL}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [12]$$

The value of f in formula [12] varies considerably with the roughness of the pipe, with its diameter, and probably to some extent with the velocity of flow. For air and other gases f may be taken approximately as 0.005.

For convenience in calculation, H may be expressed in terms of difference in pressure in lb. per sq. in., or $H = 144\ (p_1 - p_2) \div W$, and the diameter d in inches. Therefore,

$$v = 4.0103\sqrt{\frac{144(p_1 - [illegible]}{fwL}}\ [illegible] = 13.892\sqrt{[illegible]} \qquad [13]$$

The quantity of flow in cubic feet per minute is $Q = 60AV$, where A = the area in sq. ft. = $60 \times 0.7854 \times d^2 \div 144$, whence

$$Q = 4.546 \sqrt{\frac{\;}{\;}} \quad . \quad [14]$$

which is the common formula for flow of any liquid or gas when Q is in cubic feet per minute measured at the density w corresponding to the higher pressure p_1. To reduce this to the equivalent volume of air at atmospheric pressure, $Q_a = Q \times (p_1/14.7)$.

The weight flowing per minute is

$$Qw = W = c\sqrt{\frac{u}{\;}}$$

Values of c corresponding to different values of f are as follows:

f.........	0.003	.0035	.004	.0045	.005	.0055	.006	.0065	.007	.0075
c.........	83.0	76.9	71.9	67.8	64.3	61.3	58.7	56.4	54.7	52.4

The experimental data from which the values of c and f for air and gas may be determined are few in number and of doubtful accuracy. Probably the most reliable are those obtained by Stockalper at the St Gothard tunnel. Unwin found from these data that the value of f varied with the diameter and that it might be expressed by the formula $f = 0\,0028(1 + 3\,6/d)$, d being taken in inches.

	1	2	3	4	6	12	24	48 in.
f =	0.013	.0078	.0062	.0053	.0045	.0036	.0032	.0030
c =	40.0	51.3	57.9	62.3	67.9	75.3	80.1	82.8

Unwin's formula may take the form, $Q = K\sqrt{\frac{(p_1 -}{wL(1}}$ [16]

in which $K = 4\,546\sqrt{1 \div 0\,0028} = 85.9$. This is practically the same as Babcock's formula for steam, in which f is taken at 0.0027, giving $K = 87.5$.

FORMULAS FOR FLOW WITH LARGE DROP IN PRESSURE.—The above formulas are based on the assumption that the drop in pressure is small, and that, therefore, the density remains practically constant during the flow. When the drop is large the density decreases with the pressure and the velocity increases. Church (Mechanics of Engineering, p. 791) and Unwin (*Ency. Brit.*, 11th ed., vol. xiv, p 67), develop formulas for compressible fluids with large drop of pressure and increasing velocity. The temperature is assumed to be constant, the heat generated by friction balancing the cooling due to the work done during expansion.

Church's formula: [17]

Unwin's formula: $\sqrt{\frac{gRTd\,(}{4fl}}\quad p_1^2$ . . . . [18]

In these formulas V = velocity, ft. per sec.; Q = volume, cu. ft. per sec at the pressure p_1; $g = 32.2$; R = the constant in the formula $PV = RT$ (see Thermodynamics) = 53 32 for air; d = diam., and L = length, ft.; p_1, p_2 = absolute pressures in lb. per sq. ft.; w = density, lb. per cu. ft.; T = temperature, deg. F + 459.6. The value of f is given by Church as from 0.004 to 0.005. Unwin makes it vary with the diameter as stated above.

These two formulas give identical results when the value of f is taken the same in both, for $RT/p_1^2 = 1 \div wp_1$.

J. E. Johnson, Jr. (*Am. Mach.*, July 27, 1899) gives formula [17] in a simpler form as follows.

where p_1 and p_2 are the initial and final pressures in lb. per sq. in.; Q = volume of free air (that is the volume reduced to atmospheric pressure) in cubic feet per minute; d = the diameter of the pipe, in ; L = the length, ft.; and K = a numerical coefficient which from the Mt. Cenis and St. Gothard experiments has a value of about 0 0006. E. A. Rix, in a paper on the Compression and Transmission of Illuminating Gas, read before the Pacific Coast Gas Assoc., 1905, uses formula [19] with a coefficient of 0.0005, which he considers more nearly correct than 0.0006. For gas the velocity varies inversely as the square root of the density, and for gas of a density G, relative to air as 1, Rix gives the formula

$$p_1^2 - p_2^2 = 0.0005\sqrt{G} \times Q^2L/d^5 \quad . \quad . \quad . \quad [20]$$

If formula [17] is translated into the same form as [19], taking $f = 0.005$, $w = 0.07608$ for air at 62° F., and atmospheric pressure, 14.7 lb. per sq. in., the value of K is 0.00054. A more convenient form is D'Arcy's:

$$Q_a = C_1\sqrt{(p_1^2 - p_2^2)d^5/L} \quad . \quad . \quad . \quad [21]$$

in which $C_1 = \sqrt{1/K}$. With K in formula [19] taken at 0.0006, $C_1 = 40.8$. With f in formula [17] taken at 0.005, $C_1 = 43.0$.

Note that formula [17] gives Q in cubic feet per second, measured at the pressure p_1, while in formula [19] Q_a is in cubic feet per minute reduced to atmospheric pressure. Both Church and Johnson assume that the flow varies as $\sqrt{d^5}$, the coefficients f and K being independent of the diameter. In this respect their formulas are faulty, for, as Unwin shows, the coefficient of friction is a function of the diameter.

The relation between the results given by these formulas and those given by the common formulas is the relation between $\sqrt{p_1^2 - p_2^2}$ and $\sqrt{p_1 - p_2}$. Taking p_1 (in any unit) as 100, and different drops in pressure, the relative results are as follows:

Pressure drop	1	10	20	40	60	80
Values of p_2	99	90	80	60	40	20
$\sqrt{p_1^2 - p_2^2} \div \sqrt{p_1 - p_2}$	14.1	13.8	13.4	12.2	11.8	10.8
Ratio, 14.1 = 100	100	97.6	95.0	86.5	83.7	76.6

It thus appears that the calculated result by formula [19] is not more than 5% less than that calculated by the common formula, when the same value of f is used, if the drop in pressure is not greater than 20% of p_1.

COMPARISON OF DIFFERENT FORMULAS may be made by applying them to the data of the St. Gothard experiments, as in Table 18. The value of Q is given as reduced to atmospheric pressure, 14.7 lb per sq. in. and 62° F. The length of the 7.87-in. pipe was 15,092 ft., and that of the 5.91-in. pipe, 1712.6 ft. The mean temperature of the air in the large pipe was 70° F. and in the small pipe 80° F.

In Table 18, the figures in the columns headed (14), (16) and (21) refer respectively to:

The common formula, $$c\sqrt{\frac{(p_1 -}{wL}} \qquad [14]$$

Unwin's formula, $$K\sqrt{\frac{(p_1 - p_2)d^5}{wL(1 + 3.6/d)}}. \qquad [16]$$

D'Arcy's formula, [21]

where Q_1 = cu. ft. per min. at pressure p_1; Q_a = cu. ft. per min. reduced to atmospheric pressure = $Qp_1 \div 14.7$.

Table 18.—Comparison of Different Formulas as Applied to St. Gothard Experiments

Diameter, in.	Mean Velocity, ft. per sec.	Cu. ft. per min. Q	Lb. per sec.	Absolute Pressures, lb. per sq. in.		Coefficient in Formula			Ratio of Coefficient to Average Value		
				p_1	p_2	(14) c	(16) K	(21) C_1	(14)	(16)	(21)
7.87	19.3	2105	2.669	82.32	77.03	76.0	89.6	51.3	1.06	1.03	1.09
7.87	16.3	1401	1.776	63.95	60.71	73.5	86.5	49.3	1.02	0.99	1.05
7.87	15.6	1169	1.483	56.45	53.66	70.2	82.8	46.0	0.98	0.95	0.98
5.91	37.1	2105	2.669	77.03	73.50	74.8	94.9	44.5	1.04	1.09	0.95
5.91	29.3	1169	1.483	53.66	52.04	65.5	83.1	43.6	0.91	0.95	0.93
Average						72.0	87.4	46.9			

This comparison shows that no one of the three formulas fits the St. Gothard experiments better than any other; each one when applied with the average value of its coefficient may give a result that differs as much as 9% from the observed result.

ARSON'S EXPERIMENTS.—Unwin quotes some experiments by A. Arson on the flow of air through cast-iron pipes which showed the coefficient of friction to vary with velocity. For a velocity of 100 ft. per sec., and without much error for higher velocities, Unwin finds that values of f agree fairly with the formula $f = 0.005\ (1 + 3.6/d)$. His figures for values of f, translated into values of c for use in the common formula, are:

Diameter of pipe, inches	1.97	3.19	4.06	10	12.8	19.7
Values of c: V = 10 ft. per sec.	35.7	39.4	39.8	49.2	52.8	64.7
50 " "	38.6	42.5	45.0	51.5	55.7	65.2
100 " "	41.3	45.5	46.0	53.6	56.4	65.4

The values of c for the same diameter with $f = 0.0028\ (1 + 3.6/d)$, as deduced by Unwin from Stockalper's experiments are: 51.4, 57.9, 62.3, 73.7, 75.9, 79.1. Unwin states that Stockalper's pipes were probably less rough than Arson's. The values of c from Stockalper's experiments range from 21 to 37% higher than those calculated from the formula derived from Arson's experiments.

USE OF THE FORMULAS.—It is evident from the above comparisons that any formula for the flow of air or gas must be considered as giving only a rough approximation, and that an observed result may differ as much as 40% from that calculated by a formula. This difference is due to variations in the roughness of pipes, to error in measurements

of the actual flow, and to the fact that the coefficients of the several formulas are based on too few experiments. Unwin's formula for moderate drop,

$$Q = 87 \cdot \sqrt{\frac{(p_1 - p_2)d^5}{(1 + 3.6/d)}} \qquad [22]$$

is probably the best one to use for all cases where the drop in pressure does not exceed 20% of the absolute initial pressure, and Johnson's formula,

for cases where the drop is larger and the pipes are not less than 12 in. diameter. For smaller pipes it is best to use the term $(1 + 3.6/d)$ after L in the denominator. These formulas, with the coefficients given, apply only to straight pipes with a fairly smooth interior surface. For crooked or rough pipes it may be well to use the common formula with the coefficients derived from Arson's experiments, given above.

Another comparison of the three formulas [14], [16] and [21] may be made by applying them to some extreme cases, as follows: The initial pressure is taken at 100 lb. absolute per sq. in., the corresponding density is 0.5176 lb. per cu. ft.; diameters are assumed at 1 in. and 48 in., the drop in pressure 1 lb. and 40 lb. and the length 100 ft. and 40,000 ft., making eight cases in all. A ninth case is taken with intermediate values; diameter, 10 in.; length, 1,000 ft.; and drop, 1 lb. The results are given in Table 19. Those obtained from formula [21] have been reduced by dividing them by the ratio (100/14.7) to obtain Q. In formula [14], c is taken at 72, the average figure from the St. Gothard experiments.

Table 19.—Comparison of Formulas for Flow of Air by Application to Extreme Cases

Diam., in.	1				48				10
(p_1-p_2), lb.	1		40		1		40		1
L, ft.	100	40,000	100	40,000	100	40,000	100	40,000	1,000
Formula	Cubic Feet of Air per Minute at the Pressure p_1								
[14]	10.08	0.50	63.3	3.16	159,800	7,990	1,010,000	50,500	1,008
[16]	5.64	0.28	35.7	1.78	186,200	9,310	1,178,000	58,900	1,037
[21]	9.75	0.49	55.3	2.76	155,600	7,778	882,300	44,110	974
	Ratio of Results to Unwin's = 1								
[14]	1.79	1.79	1.78	1.78	0.86	0.86	0.86	0.86	0.96
[21]	1.73	1.75	1.55	1.55	0.84	0.84	0.75	0.75	0.94

These figures show that while the three formulas agree fairly well for the 10-in. pipe with 1-lb. drop in 1000 ft., they show wide disagreements when a great range of diameters, lengths, and drops in pressure are taken. For the 1-in. pipe Unwin's figures (formula 16) are from 35 to 45% lower than those given by formulas [14] and [21], but they are not, therefore, certainly too low. A check on them is supplied by Culley and Sabine's experiments on 2 1/4-in. lead pipes, 2000 to nearly 6000 ft. long, quoted by Unwin, which gave a value of $f = 0.07$. Unwin's formula, $f = 0.0028\ (1 + 3.6/d)$, gives $f = 0.0073$. The corresponding values of c in the common formula are 54.7 and 53.2.

FORMULA FOR FLOW OF AIR AT LOW PRESSURES.—For ventilating and similar purposes, air is usually carried at pressures only slightly above that of the atmosphere. Pressures are measured in inches of water column or in ounces per square inch above atmospheric pressure. For smooth and straight circular pipes, probably the best formula to use is Unwin's,

$$Q = 87 \quad \frac{(p_1 -}{wL(1 + 3.6/d)},$$

the coefficient 87 being derived from the St. Gothard experiments on compressed air. To put the formula into a more convenient form for low pressures, let h = head or difference in pressures measured, in. of water column = 27.712 $(p_1 - p_2)$, and take w = 0.07493 = density of air, lb. per cu. ft. at 70° F. and atmospheric pressure. Then

$$Q = 87 \times \sqrt{\quad h \qquad 1 \quad}$$

or $$Q = C\sqrt{hd^5/L}. \qquad [25]$$

in which C is a coefficient varying with the diameter, values for different diameters being given in Table 20. For other temperatures and pressures, the flow varying inversely as the square root of the density, the figure 0.07493 in the above equation should be replaced by $0.07493 \times \frac{p}{14.7} \times \frac{530}{460 + T}$, in which p = absolute pressure, lb. per sq. in.; T = deg. F.; Q = quantity of air, measured at given pressure and temperature, cu. ft. per min.

In Table 20, Q = cu. ft. per min. $= C\sqrt{hd^5/L}$, h = drop in pressure, in. of water column, d = diam., in., L = length of pipe, ft., C = a coefficient varying with the diameter. The values of C in the table are based on air at atmospheric pressure and 70° F., and the values of Q are calculated for the same pressure and temperature and for a drop of 1 in. of water column in 100 ft.

Table 20.—Values of C and Q, for Different Values of d

d	C	Q	d	C	Q	d	C	Q	d	C	Q
4	43.9	140	10	51.8	1,637	22	56.0	12,700	42	57.9	66,240
5	46.1	257	12	53.0	2,642	24	56.3	15,880	48	58.2	92,930
6	47.7	421	14	53.9	3,950	26	56.6	19,500	54	58.4	125,200
7	49.1	636	16	54.6	5,585	28	56.8	23,580	60	58.6	163,500
8	50.1	908	18	55.1	7,579	30	57.1	28,130	66	58.8	208,000
9	51.0	1,240	20	55.6	9,946	36	57.6	44,760	72	58.9	259,200

For any other pressure drop than 1 in. of water column per 100 ft., multiply Q by the square root of the drop, or by the factor given below:

Drop, h	0.5	2	3	4	6	8	10	12	14	16	18	20
Factor	0.71	1.41	1.73	2	2.45	2.83	3.16	3.46	3.74	4	4.24	4.47

For drop in oz. per sq. in. (1 oz. = 1.732 in. of water) the factors are:

Drop, oz.	0.5	1	2	3	4	5	6	7	8	9	10	12
Factor	0.93	1.32	1.86	2.28	2.63	2.94	3.22	3.48	3.72	3.95	4.16	4.56

B. F. Sturtevant Co. gives the following formula for loss of pressure, oz. per sq. in.

$$p_1 = \frac{Lv^2}{25,000\,d}; \quad v = \sqrt{\frac{25,000\,dp_1}{L}}; \quad d = \sqrt{\frac{0.0000025\,Lv^2}{p}}$$

where p_1 = loss of pressure, oz. per sq. in.; v = velocity, ft. per sec.; d = diam., in.; L = length, ft. From the value of v we obtain the flow in cu. ft. per min.

$$Q = 60\,av = 60 \times 0.7854\,d^2 \div 144 \times \sqrt{(25,000\,dp_1/L)} = 51.74\,(p_1\,d^5/L) \quad [26]$$

If drop is in. of water column, h, then $Q = 39.24\sqrt{hd^5/L}$. . . . . [27]

The value of Q from this formula is 9% less than that given in the above table for a 4-in. pipe, and 33% less for a 72-in. pipe.

Table 21.—Flow of Compressed Air in Pipes of Standard Lap-welded Sizes

FLOW IN RECTANGULAR PIPES.—To economize space, air pipes for ventilating purposes are commonly made of rectangular instead of circular section. No records of experiments on the flow of air in such pipes are available, but a fair estimate of their capacity as compared with that of circular pipes of the same area may be made on the assumption that they follow the law expressed by Chezy's formula for flow of water, viz.: that the flow is proportional to the square root of the mean hydraulic radius r, which is defined as the quotient of the area divided by the perimeter of the wetted surface. For a circular pipe $r = 1/4 \times$ diameter in feet, and for a square pipe of the same area, $r = 0.222\,d$. For rectangles of the same area, r decreases as the ratio of the longer to the shorter side increases. For different proportions of sides, the values of r and the ratio of $\sqrt{r}$ to the value of $\sqrt{r_1}$ (hydraulic radius of a circular pipe of the same area) are as below.

Ratio of sides....	(circle)	1 (sq.)	1.5	2	3	4	5	6
r = ...	0.25	0.222	0.217	0.209	0.192	0.177	0.165	0.155
Ratio $\sqrt{r} \div \sqrt{r_1}$..	1	0.942	0.932	0.914	0.875	0.842	0.813	0.787

That is, a square pipe has 94% of the carrying capacity of a circular pipe of the same area, and a rectangular pipe whose sides are in the ratio of 6 : 1 has only 79% of the capacity of a circular pipe of the same area.

Formula $Q = c$. Q = cu. ft. per min. measured at pressure p_1 and 62° F. $p_1 - p_2$ = lb. per sq. in.; w = density, lb. per cu. ft.; d = diam. in.; L = length, ft.

Values of $c = 87\sqrt{\dfrac{1}{1 + 3.6/d}}$ are as follows:

Diam., in........	1/2	3/4	1	1 1/4	1 1/2	2	2 1/2	3	3 1/2
c = ...	33.4	37.5	41.3	45.8	48.4	52.5	55.5	59.0	61.3
Diam., in........	4	4 1/2	5	6	7	8	9	10	11
c = ...	63.2	64.8	66.5	68.7	70.7	72.2	73.4	74.5	75.5
Diam., in........	12	13	14	15	17 O.D.	18 O.D.	20 O.D.	22 O.D.	24 O.D.
c = ...	76.3	77.1	77.7	78.2	78.7	79.1	79.8	80.4	80.9

For any other drop than 1 lb. per sq. in. in 1000 ft. length, multiply the figures in the table by the square root of the drop.

Table 22.—Volume of Air Transmitted in Cubic Feet per Minute in Pipes of Various Diameters

Formula $Q = (0.7854/144)\, d^2 v \times 60$

30	9.8	39.3	88	157	245	353	628	982	1414	2513	3927	5655

EFFECT OF BENDS IN PIPES.—The Norwalk Iron Works Co., South Conn., gives the effect of bends in pipes as follows, D being the diameter of the and L the length of straight pipe diameters whose effect is equivalent to the bend:

Radius of elbow.	$5D$	$3D$	$2D$	$1\,1/2\,D$	$1\,1/4\,D$			
L..............	7.85	8.24	9.03	10.36	12.72	17.51	35.09	121.2

E. A. Rix and A. E. Chodzko, in their treatise on compressed air (1896) give the following as the loss in pressure through a 90-deg. bend, V being the velocity of air at

entrance, ft. per sec., R the radius of bend, in., and D the internal diameter of pipe, in:

		2	3	4	5
Loss in lb. per sq. in..........	$0.005V^2$	$0.0022V^2$	$0.0016V^2$	$0.0013V^2$	$0.0012V^2$

REDUCTION OF PRESSURE BY GLOBE VALVES, TEES AND ELBOWS.—The reduction of pressure produced by globe valves is the same as that caused by the addition of lengths of straight pipe, as calculated by the formula

$$\text{Additional length of pipe, inches} = 114\,d \div \{1 + (3.6 \div d)\} \quad . \; . \; . \; . \quad [28]$$

where d is the pipe diameter, in. The reduction of pressure produced by elbows and tees is equal to 2/3 of that caused by globe valves. These additional lengths of pipe for globe valves, elbows and tees must be added in each case to the actual length of straight pipe. Thus a 6-in. pipe 500 ft. long with 1 globe valve, 2 elbows and 3 tees would be equivalent to a straight pipe $500 + 36 + (2 \times 24) + (3 \times 24) = 656$ ft. long. See Table 23.

Table 23.—Pipe Lengths Equivalent to Valves and Fittings

Diam. of Pipe, in.	Additional Length, ft.		Diam. of Pipe, in.	Additional Length, ft.		Diam. of Pipe, in.	Additional Length, ft.	
	Globe Valves	Elbows and Tees		Globe Valves	Elbows and Tees		Globe Valves	Elbows and Tees
1	2	2	4	20	13	12	88	59

3 1/2	16	11	10	70	47	24	200	134

MEASUREMENT OF AIR VELOCITY BY ANEMOMETER.—Tests by B. Donkin, Jr. (Inst. Civil Engrs., 1892) on pipes 8 to 20 in. diam., with air velocities of 140 to 690 ft. per min., showed the anemometer to have an error ranging from 14.5% fast to 10% slow,

8 ft. square

1712	1795	1859	1329
1622	1685	1782	1091
1477	1344	1524	1049
1202	1356	1203	1333

Average = 1469

5 × 8 ft.

1170	1209	1288
948	1104	1177
1134	1049	1106

Average = 1132

the percentage of error not being constant. In a 24-in. pipe, air velocity 73 ft. per min., as measured by the descent of a gas holder of 1622 cu. ft. capacity, showed as 44 to 63 ft. per min. on the anemometer, or 13.6% to 39.6% slow. See *Eng. News*, Dec. 22, 1892. The impossibility of measuring the true quantity of air by an anemometer held in one position is shown by the accompanying diagram (Wm. Daniel, *Proc.* Inst. M. E., 1875), of the velocities of air at different points in two airways in a mine.

The anemometer is most frequently used to determine the velocity of air leaving a register or air vent, where the velocity is low. It should be frequently calibrated, and readings made over a series of squares covering the area over which velocity is measured, the average being used in calculations. (See Fan Engineering, Buffalo Forge Co., p. 74).

Tests by L. E. Davies at Armour Inst. of Tech. (*Jour.* A. S. H. V. E., Jan., 1930, April, 1931), developed the formula $Q = 0.5\,CV(A + a) = 0.5\,CVA(1 + p)$ *for supply registers*, with the anemometer in direct contact with the register face and the dial facing the operator. *For exhaust systems*, best results were given by $Q = KVA$, the anemometer being held against the grille, with the dial facing it. In both formulas, Q = cu. ft. of air per min.; V = average of corrected velocity readings, ft. per min.; A = gross area of register or grille, sq. ft.; a = net free area of register, sq. ft.; $p = a/A$ expressed as a decimal; C and K = factors varying with velocity of air through register or grille. Values of C and K are as follows:

V (average)......	150	200	300	400	500	600	700	800
C (supply grilles).	0.952	.957	.967	.977	.985	.992	.998	1.000
K (exhaust grilles)	0.762	.772	.789	.806	.820	.828	.832	.....

EQUALIZATION OF PIPES.—It is frequently desired to know what number of pipes of a given size are equal in carrying capacity to one pipe of a larger size. At the

same velocity of flow the volume delivered by two pipes of different sizes is proportional to the squares of their diameters; thus, one 4-in. pipe will deliver the same volume as four 2-in. pipes. With the same head, however, the velocity is less in the smaller pipe, and the volume delivered varies about as the square root of the fifth power (*i.e.*, as the 2.5 power).

Table 24.—Loss of Pressure in Compressed Air Transmission

For longer or shorter pipes the friction loss is proportional to the length, *i.e.*, for 500 ft., $1/2$ of the above; for 4000 ft., four times the above, etc.

4. AIR METERS

DIRECT READING TYPE.—An example of a direct reading meter is the small "Tool-om-eter" made at Plainfield, N. J., which may be used to detect and measure leakage in air lines, valves, hose, cocks, etc., to determine actual compressor capacity as compared with nominal rating or displacement, show where air goes after it is compressed and furnish the facts on disputed questions. The scale of the meter is calibrated to read directly in cubic feet of air per minute, when the gage pressure of the air passing the meter is at 80 lb. per sq. in. For pressures greater or less than 80 lb. per sq. in., a pressure factor is used from a table furnished by the maker. The meters are calibrated in terms of air at 14.7 lb. per sq. in. and 60° F. or 520° absolute temperature. If the air is warmer, the meter will over-register approximately 1% for each 11° F. in excess of 60° F. It ordinarily is not necessary to take account of this for pneumatic tools, etc., as their air consumption is also influenced by temperature. For close measurements where temperature must be considered, multiply the meter readings by the temperature coefficient $K = \sqrt{520 \div (T + 460)}$, where T = temperature, deg. F., of the air passing through the meter.

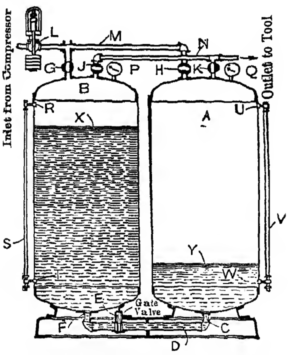

Fig. 4. Water-displacement Meter

WATER DISPLACEMENT TYPE METERS.—(For further information see Peele's Compressed Air Plant, 5th Edition, 1930, Chap. xxv.) There are several forms of this type. The following apparatus will serve to illustrate the principles involved. Fig. 4 is a section through the meter. Fig. 5 gives diagrams ...fferent arrangements of the valves. The meter consists of two tanks, A and B, of the same size and of known volume, mounted side by side. Their upper portions are connected to the source of supply by the inlet pipe M, the opening into tank A being controlled by valve H, and into tank B by valve G. The outlet line also is connected to the top of the tanks by pipe N, the opening into tank A being controlled by valve K, and to tank B by

valve J. The tanks are connected at the bottom by pipe D, in which is a valve E, preferably a quick-opening gate valve. The tanks have gage-glasses V and S and pressure gages Q and P. The inlet line has a pressure-reducing valve L which, while not essential, is a convenience, as it prevents fluctuations in inlet pressure from affecting the readings of the meter, and allows the meter to be used on pressures lower than that of the source of supply. The reducing valve L is set for the desired pressure, connecting the machine whose capacity is to be measured to the outlet line. The valves are set as shown in diagram 1 of Fig. 5, the top part of each tank being open to both inlet and outlet line. Valve E being closed, the water is held stationary in each tank. Air from the inlet line will then pass through the tank to the outlet line and through the machine connected thereto. The meter thus acts as a receiver and has no effect on the air passing through it.

To measure the volume of air used, the throttle valve on the machine is first closed. When the tank pressures equalize, as indicated by the gages, the valves are changed to the position shown in diagram 2 of Fig. 5. Tank B is now in communication with the inlet line, but cut off from the outlet. Tank A is in communication with the outlet line, but closed to the inlet. The level of the water in the gage-glass S is noted, and the valve E opened. The valves are now in the position shown in Fig. 4 and the meter is ready to measure the volume of air passing through the machine. On opening the throttle of the machine, the air in tank A passes through the outlet to the machine. This causes a reduction of pressure in tank A. The air in tank B now causes the water to flow from B to A, equalizing the pressures in both, the pressure in B being maintained by the air

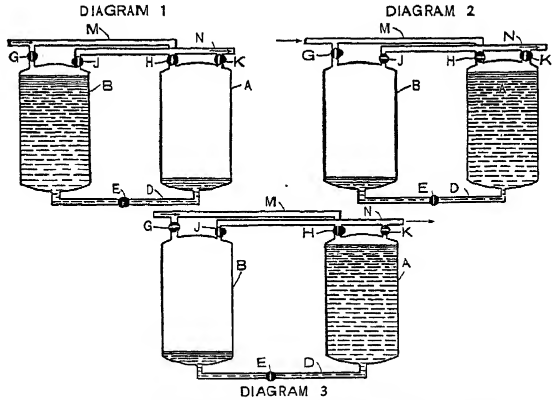

FIG. 5. Valve Operation of Water-displacement Meter

from the inlet line N. This flow of water causes a drop in the water level in gage-glass S. At the end of the interval during which it is desired to measure the volume of air used, valve E is quickly closed, preventing further flow of water. The drop of level in gage-glass S is now measured, from which the volume of air used is calculated.

When the water level rises to the top of tank A, the valves in inlet and outlet lines are thrown to the position shown in diagram 3 of Fig. 5. The meter is now ready for further measurements, after the pressure in the tanks has been equalized and the valve E opened. The conditions are now reversed and the water will flow from tank A to tank B, readings being taken on gage-glass V. In practice the valves can be manipulated with such rapidity that it is unnecessary to stop the machine being tested, and any number of readings can be taken.

The meter readings are taken by using a graduated board placed behind the gage-glasses, one graduation being used for each pressure. On beginning a test, the height of water in each gage-glass is marked, and at the end the drop is measured on the graduated board, thus giving the volume of air used.

Other forms of water-displacement meter have been devised. Among them is a simple single-tank meter, that has been satisfactorily used by the Sullivan Machinery Co. (For details of operation and computation of results, see Peele's Compressed Air Plant, 5th Ed., pp. 503–5.)

LOSS OF ENERGY IN THE PRODUCTION AND USE OF COMPRESSED AIR.—The practical results of Charles's law are (Zahner Transmission of Power by Compressed Air): 1. As the heat of compression increases the volume of the air, the pressure must be carried higher in the compressor cylinder to produce a given volume at a given pressure, after it has returned to normal atmospheric temperature. The work expended in producing this excess pressure is work lost. 2. The heat generated reacts upon the air under compression, and increases the pressure due merely to the reduction of volume. As the compressed air, before it is used, usually has time to cool to the temperature of the surrounding atmosphere, the mechanical equivalent of the dissipated heat is work lost.

Two other statements are deduced from what precedes: 1. Under constant pressure the air varies directly as the absolute temperature, and, at constant volume the absolute p directly as the absolute temperature. These relations are expressed by $(p_1 v_1)/t = p_2$ a constant. This constant is found as follows: Since the density of a given weight of air is inversely proportional to its volume, $v_1 = (1/0.08073)$, 0.08073 being the weight in pounds of 1 cu. ft. of dry air, at sea-level pressure (14.7 lb.) and 32° F. The normal atmospheric pressure per sq. ft. = 14.7 $\times$ 144 = 2116.8 lb. Hence, if, by applying heat, 1 cu. ft. be expanded to 2 cu. ft., the work done against atmospheric pressure, per lb. of air, will be $(2116.8 \times 1)/0.08073 = 26{,}220$ ft.-lb. To double the volume (according to Boyle's law) would require the expenditure of 491.4° F. of heat. Hence, in raising the temperature 1° F., the external work done by expansion is

$$(p_1 v_1/t) = (26{,}220/491.4) = 53.35 = R.$$

The heat generated during compression to different pressures is shown in Table 26, the volume at normal atmospheric pressure being 1, at a temperature of 60° F.

ISOTHERMAL AND ADIABATIC COMPRESSION.—If the air during c be kept at constant temperature, the heat being abstracted as fast as it is produced, the compression curve of an indicator diagram from the cylinder is an isothermal curve, following Boyle's law, $(p_2/p_1) = (v_1/v_2)$ = constant.

If the temperature be allowed to rise unchecked during compression, without transference of heat by either radiation or cooling devices, the pressure rises faster than the volume diminishes, and p_2/p_1 is greater than v_1/v_2. The curve of the diagram is then an adiabatic curve, the equation of which is $(p_2/p_1) = (v_1/v_2)^k$.

The value of k for air is found as follows: The heat required to increase the temperature of 1 lb. of air 1° F. at constant pressure, is its *specific heat at constant pressure*. It includes both the external work of expansion and the internal work of raising its temperature. Its value as given by Regnault is 0.2375 B.t.u. per lb. Therefore, the heat required to raise the temperature only, without external work, is 0.2375 − 0.0686 (work of expansion) = 0.1689 B.t.u. per lb. This is the *specific heat of air at constant volume*. In the expression for adiabatic compression, the exponent k is therefore the ratio of these specific heats, or 0.2375/0.1689 = 1.406.

FORMULAS FOR ADIABATIC COMPRESSION OR EXPANSION OF AIR (OR OTHER SENSIBLY PERFECT GAS).—Let air at an absolute temperature T_1, absolute pressure p_1, and volume v_1 be compressed to an absolute pressure p_2 and corresponding volume v_2 and absolute temperature T_2; or let compressed air of an initial pressure, volume, and temperature p_2, v_2, and T_2 be expanded to p_1, v_1, and T_1, there being no transmission of heat from or into the air during the operation. Then the express the relations between pressure, volume, and

$$\left(\frac{p_2}{p_1}\right)^{0.71}; \quad \frac{p_2}{p_1} = \left(\frac{v_1}{v_2}\right)^{1.41}; \quad \frac{v_1}{v_2} \qquad T_1$$

$$\frac{T_2}{T_1} = \left(\frac{v_1}{v_2}\right)^{0.41}; \quad \frac{T_2}{T_1} = \left(\frac{p_2}{p_1}\right)^{0.29}; \quad \frac{p_2}{p_1} = \left(\frac{T_2}{T_1}\right)^{3.46}$$

The exponents are derived from the ratio $c_p \div c_v = k$ of the specific heats of air at

constant pressure and constant volume. Taking $k = 1.406$, $1 \div k = 0.711$; $k - 1 = 0.406$; $1 \div (k - 1) = 2.463$; $k \div (k - 1) = 3.463$; $(k - 1) \div k = 0.289$.

WORK OF ADIABATIC COMPRESSION OF AIR.—If air is compressed in a cylinder without clearance, from a volume v_1 and pressure p_1 to a smaller volume v_2 and higher pressure p_2, work equal to p_1v_1 is done by the external air on the piston while the air is drawn into the cylinder. Work is then done by the piston on the air, first, in compressing it to the pressure p_2 and volume v_2, and then in expelling the volume v_2 from the cylinder against the pressure p_2. If the compression is adiabatic, $p_1v_1^k = p_2v_2^k =$ constant. $k = 1.406$. The work of compression of a given quantity of air is, in foot-pounds,

$$\left(\frac{v_1}{\ }\right)^{k-1} \quad \Big] \qquad p_1 v_1 \left\{ \left(\frac{p_2}{\ _1}\right)^{\frac{k-1}{k}} - 1 \right\} \qquad [3]$$

$$2.463 p_1 v_1 \left\{ \left(\frac{v_1}{v_2}\right)^{0.41} - 1 \right\} = 2.463 p_1 v_1 \quad \left(\frac{p_2}{p_1}\right)^{0.29} - 1 \Big\}. \qquad [4]$$

The work of expulsion is $W_e\ p_2 v_2 = p_1 v_1 \left(\frac{p_2}{p_1}\right)^{0.29}$.

The total work is the sum of the work of compression and expulsion less the work done on the piston during admission, and is

$$\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} - 1 \Big\} = 3. \qquad [5]$$

The mean effective pressure during the stroke is

$$k-1 \qquad 3.463 p_1 \quad \left(\frac{p_2}{p_1}\right)^{0.29} - 1 \Big\} \qquad [6]$$

p_1 and p_2 are absolute pressures above a vacuum, lb. per sq. ft.

Example.—Required the work done in compressing 1 cu. ft. of air per second from 1 to 6 atmospheres, including the work of expulsion from the cylinder.

$p_2 \div p_1 = 6$; $6^{0.29} - 1 = 0.681$; $3.463 \times 0.681 = 2.358$ atmospheres $\times 14.7 = 34.66$ lb. per sq. in. mean effective pressure, $\times 144 = 4991$ lb. per sq. ft., $\times 1$ ft. stroke $= 4991$ ft.-lb., $\div 550$ ft.-lb. per second $= 9.08$ Hp.

If R = ratio of pressures $= p_2 \div p_1$, and if $v_1 = 1$ cu. ft., the work done in compressing 1 cu. ft. from p_1 to p_2 is $3.463\, p_1\, (R^{0.29} - 1)$ ft.-lb., p_1 being taken in lb. per sq. ft. For compression at the sea level p_1 may be taken at 14 lb. per sq. in. = 2016 lb. per sq. ft., as there is some loss of pressure due to friction of valves and passages.

LOSS OF ENERGY IN THE PRODUCTION AND USE OF COMPRESSED AIR.—he practical results of Charles's law are (Zahner Transmission of Power by Compressed ir): 1. As the heat of compression increases the volume of the air, the pressure must carried higher in the compressor cylinder to produce a given volume at a given pressure, : it has returned to normal atmospheric temperature. The work expended in producing this excess pressure is work lost. 2. The heat generated reacts upon the air under compression, and increases the pressure due merely to the reduction of volume. As the compressed air, before it is used, usually has time to cool to the temperature of the surrounding atmosphere, the mechanical equivalent of the dissipated heat is work lost.

Two other statements are deduced from what precedes: 1. Under constant pressure the volume of air varies directly as the absolute temperature, and, at constant volume the absolute pressure varies directly as the absolute temperature. These relations are expressed by $(p_1 v_1)/t = (p_2 v_2)/t' = R$, a constant. This constant is found as follows: Since the density of a given weight of air is inversely proportional to its volume, $v_1 = (1/0.08073)$, 0.08073 being the weight in pounds of 1 cu. ft. of dry air, at sea-level pressure (14.7 lb.) and 32° F. The normal atmospheric pressure per sq. ft. = 14.7 × 144 = 2116.8 lb. Hence, if, by applying heat, 1 cu. ft. be expanded to 2 cu. ft., the work done against atmospheric pressure, per lb. of air, will be (2116.8 × 1)/0.08073 = 26,220 ft.-lb. To double the volume (according to Boyle's law) would require the expenditure of 491.4° F. of heat. Hence, in raising the temperature 1° F., the external work done by expansio_

$$(p_1 v_1/t) = (26{,}220/491.4) = 53.35 = R.$$

The heat generated during compression to different pressures is shown in 26, at normal atmospheric pressure being 1, at a temperature of

ISOTHERMAL AND ADIABATIC COMPRESSION.—If the air du be kept at constant temperature, the heat being abstracted as fast as it compression curve of an indicator diagram from the cylinder is an isoth lowing Boyle's law, $(p_2/p_1) = (v_1/v_2) =$ constant.

If the temperature be allowed to rise unchecked during compression, without transference of heat by either radiation or cooling devices, the pressure rises faster than the volume diminishes, and p_2/p_1 is greater than v_1/v_2. The curve of the diagram is then an adiabatic curve, the equation of which is $(p_2/p_1) = (v_1/v_2)^k$.

The value of k for air is found as follows: The heat required to increase the temperature of 1 lb. of air 1° F. at constant pressure, is its *specific heat at constant pressure*. It includes both the external work of expansion and the internal work of raising its temperature. Its value as given by Regnault is 0.2375 B.t.u. per lb. Therefore, the heat required to raise the temperature only, without external work, is 0.2375 − 0.0686 (work of expansion) = 0.1689 B.t.u. per lb. This is the *specific heat of air at constant volume*. In the expression for adiabatic compression, the exponent k is therefore the ratio of these specific heats, or 0.2375/0.1689 = 1.406.

FORMULAS FOR ADIABATIC COMPRESSION OR EXPANSION OF AIR (OR OTHER SENSIBLY PERFECT GAS).—Let air at an absolute temperature T_1, absolute pressure p_1, and volume v_1 be compressed to an absolute pressure p_2 and corresponding volume v_2 and absolute temperature T_2; or let compressed air of an initial pressure, volume, and temperature p_2, v_2, and T_2 be expanded to p_1, v_1, and T_1, there being no transmission of heat from or into the air during the operation. Then the following express the relations between pressure, volume, and temperature:

$$\frac{v_1}{v_2} = \left(\frac{p_2}{p_1}\right)^{0.71};$$

T_1 — $v_2)$, T_1 — $p_1)$ p_1

The exponents are derived from the ratio $c_p \div c_v = k$ of the specific heats of

constant pressure and constant volume. Taking $k = 1.406$, $1 \div k = 0.711$; $k - 1 = 0.406$; $1 \div (k - 1) = 2.463$; $k \div (k - 1) = 3.463$; $(k - 1) \div k = 0.289$.

WORK OF ADIABATIC COMPRESSION OF AIR.—If air is compressed in a cylinder without clearance, from a volume v_1 and pressure p_1 to a smaller volume v_2 and higher pressure p_2, work equal to p_1v_1 is done by the external air on the piston while the air is drawn into the cylinder. Work is then done by the piston on the air, first, in compressing it to the pressure p_2 and volume v_2, and then in expelling the volume v_2 from the cylinder against the pressure p_2. If the compression is adiabatic, $p_1v_1^k = p_2v_2^k$ = constant. $k = 1.406$. The work of compression of a given quantity of air is, in foot-pounds,

$$W_c \quad k - 1 \qquad \frac{}{k-1}\left\{\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} \right. \qquad [3]$$

$$\left.\left(\frac{p_2}{p_1}\right)^{0.29} - 1\right\}. \qquad [4]$$

The work of expulsion is $W_e\, p_2 v_2 = p_1 v_1 \left(\frac{p_2}{p_1}\right.$

The total work is the sum of the work of compression and expulsion less the work done on the piston during admission, and is

$$W = p_1 v_1 \, k - \qquad [5]$$

The mean effective pressure during the stroke is

$$k-1 \qquad [6]$$

p_1 and p_2 are absolute pressures above a vacuum, lb. per sq. ft.

EXAMPLE.—Required the work done in compressing 1 cu. ft. of air per second from 1 to 6 atmospheres, including the work of expulsion from the cylinder.

$p_2 \div p_1 = 6$; $6^{0.29} - 1 = 0.681$; $3.463 \times 0.681 = 2.358$ atmospheres $\times 14.7 = 34.66$ lb. per sq. in. mean effective pressure, $\times 144 = 4991$ lb. per sq. ft., $\times 1$ ft. stroke $= 4991$ ft.-lb., $\div 550$ ft.-lb. per second $= 9.08$ Hp.

If R = ratio of pressures $= p_2 \div p_1$, and if $v_1 = 1$ cu. ft., the work done in compressing 1 cu. ft. from p_1 to p_2 is $3.463\, p_1\, (R^{0.29} - 1)$ ft.-lb., p_1 being taken in lb. per sq. ft. For compression at the sea level p_1 may be taken at 14 lb. per sq. in. = 2016 lb. per sq. ft., as there is some loss of pressure due to friction of valves and passages.

800	89.5	47.2	35.7	26.3	22.0	18.1	16.2	13.9
900	93.0	48.2	37.1	27.0	22.6	18.5	16.6	14.4
1000	96.1	49.0	37.9	27.5	23.2	18.8	16.9	14.5
1200	102.8	50.7	40.3	28.8	24.8	19.9	17.7	15.0
1400	108.6	52.0						15.7
1600	113.4	53.1						16.1
1800	117.5	54.0						16.4

Theoretical horsepower required to compress adiabatically and deliver 100 cu. ft. of free air per min. = $1.511\,P_1(R^{0.29} - 1)$; P_1 = pressure of free air, lb. per sq. in., abs.

Indicator-cards from compressors in good condition and under working-speeds usually follow the adiabatic line closely. A low curve indicates piston leakage. Such cooling as there may be from the cylinder-jacket and the re-expansion of the air in clearance-spaces tends to reduce the mean effective pressure, while the "camel-backs" in the expulsion-line, due to resistance to opening of the discharge-valve, tend to increase it.

Work of One Stroke of a Compressor, with adiabatic compression, in foot-pounds,

$$W = 3.463P_1V_1(R^{0.29} - 1) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [7]$$

in which P_1 = initial absolute pressure, lb. per sq. ft. and V_1 = volume traversed by piston, cu. ft.

The work done during adiabatic compression (or expansion) of 1 lb. of air from a volume v_1 and pressure p_1 to another volume v_2 and pressure p_2 is equal to the mechanical equivalent of the heating (or cooling). If t_1 is the higher and t_2 the lower temperature, deg. F., the work done is $c_vJ(t_1 - t_2)$ foot-pounds; c_v = specific heat of air at constant volume = 0.1689, and J = 778, c_vJ = 131.4.

The Work During Compression is

$$v_1\left[\left(\frac{p_2}{p_1}\right)^{0.29} - 1\right], \quad . \quad . \quad . \quad . \quad [8]$$

R_a being the value of pv ÷ absolute temperature for 1 lb. of air = 53.315.

The Work During Expansion is

$$W_e \quad \left[1 - \left(\frac{p_2}{p_1}\right)^{0.29}\right] \qquad \left[\left(\frac{p_1}{p_2}\right)^{0.29} - 1\right], .$$

in which p_1v_1 are the initial, and p_2v_2 the final, pressures and volumes.

Values of Exponent k.—In the above equations, k is taken at its adiabatic value = 1.406. In practice, this value is closely approached for ordinary single-stage dry compressors, but for large, slow-speed, single-stage compressors in good order, k may become 1.3 to 1.35, and for large, multi-stage compressors it may become as low as 1.2 to 1.25.

STAGE COMPRESSION.—Work (foot-pounds) in the low-pressure or intake cylinder is W_1, and in the high-pressure cylinder, W_2. The compression in each cylinder is assumed to be adiabatic, but an intercooler between them is supposed to reduce to normal temperature the partly compressed air entering the high-pressure cylinder.

$k-1$

First stage . . [10]

. . . [11]

For a given total ratio of pressures, R, the work will be a minimum when it is equally divided between the two cylinders. Assuming perfect intercooling, $p_1 v_1 = p_2 v_3$; whence, by substitution and reduction, and making $k = 1.406$, the work for two-stage compression i

$+ W_2 = 2 \times 3.46$; = 6.9 [12]

Dividing this expression by v_1 gives the mean effective pressure reduced to the low-pressure cylinder, $P_m = 6.92 p_1 (R^{0.145} - 1)$.

For three-stage compression,

$$W_1 + W_2 + W_3 = 10.389\, p_1 v_1 (R^{0.0962} - 1). \quad \ldots \quad [13]$$

Table 29.—Horsepower to Compress 1 Cu. Ft. of Air per Minute from Atmospheric Pressure (14.696 lb.) to Various Gage Pressures—2-stage Compression

Horsepower required to compress and deliver 100 cu. ft. free air per min.:

For two-stage, $\mathrm{Hp.} = 3.022\,p_1(R^{0.145} - 1)$ . . . . [14]

For three-stage, $\mathrm{Hp.} = 4.53\,p_1(R^{0.0962} - 1)$. . . . . . . [15]

EXAMPLE.—To compress 100 cu. ft. free air per min. in two stages, from 1 to 6 atmospheres, $p_1 = 14.7$ and $R = 6$; hence, $3.022 \times 14.7 \times 0.2964 = 13.17$ Hp.

TO FIND THE INDEX OF THE CURVE OF AN AIR DIAGRAM.—If P_1V_1 be pressure and volume at one point on the curve, and PV the pressure and volume at another point, then $\frac{P}{P_1} = \left(\frac{V_1}{V}\right)^x$, in which x is the index to be found. Let $P \div P_1 = R$, and $V_1 \div V = r$; then $R = r_x$; $\log R = x \log r$, whence $x = \log R \div \log r$. (A graphic method is described in *Am. Mach.*, June 21, 1900.)

COMPRESSED-AIR ENGINES, ADIABATIC EXPANSION.—Let the initial pressure and volume taken into the cylinder be p_1 lb. per sq. ft. and v_1 cu. ft.; let expansion take place to p_2 and v_2 according to the adiabatic law $p_1 v_1^{1.41} = p_2 v_2^{1.41}$; then at the end of the stroke let the pressure drop to the back-pressure p_3, at which the air is exhausted. Assuming no clearance, the work done by 1 lb. of air during admission, measured above vacuum, is p_1v_1, the work during expansion is $2.463\ p_1 v_1\{1 - (p_2/p_1)^{0.29}\}$, and the negative or back-pressure work is $-\,p_3 v_2$. The total work is

$$p_1 v_1 + 2.463\ p_1 v_1\{1 - (p_2/p_1)^{0.29}\} - p_3 v_2,$$

and the mean effective pressure is the total work divided by v_2.

If the air is expanded down to the back-pressure p_3 the total work is

$$3.463\ p_1 v_1\{1 - (p_3/p_1)^{0.29}\},$$

or, in terms of the final pressure and volume, $3.463\,p_3 v_2\{(p_1/p_3)^{0.29} - 1\}$, and the mean effective pressure is $3.463\,p_3\{(p_1/p_3)^{0.29} - 1\}$.

The actual work is reduced by clearance. Then the product of the initial pressure p_1 by the clearance volume is to be subtracted from the total work calculated from the initial volume v_1, including clearance. (See p. 7–13 under "Steam-engine.") For further data on air engines see Peele's Compressed Air Plant, 5th ed., 1930, Chap. xvi.

CENTRAL COMPRESSED AIR PLANTS.—Independent plants, selling large volumes of compressed air, are not common. The most extensive in 1932 are those of the Victoria Falls and Transvaal Power Co., furnishing metered air to groups of deep Johannesburg gold mines, South Africa. Turbo-compressors are used, having unit capacities of 12,000 to 60,000 cu. ft. of free air per min., compressed to 135–170 lb. per sq. in. gage; total, about 300,000 Hp. See *Trans.* So. African Inst. of Engrs., Jan., 1925, also p. 1–51, herein.

2. AIR COMPRESSION AT ALTITUDES

EFFECT OF ALTITUDE ON COMPRESSOR CAPACITY.—Other things being equal, the volumetric efficiency of a compressor depends upon cylinder clearance and compression ratio. In a single-stage compressor, since the compression ratio depends on the discharge and intake pressures, it varies with the altitude for given discharge gage pressure. See Fig. 8. The change of volumetric efficiency with compression ratio is due to the re-expansion of some of the air trapped in the clearance space, and has no relation to the relative density of the air at the altitude, nor to any so-called "equivalent free air at sea-level." The volumetric efficiency is expressed as the percentage of "free air" delivered, measured at the temperature and pressure of the compressor intake, ordinarily depending on the local atmospheric conditions.

In the case of a compound compressor, the volumetric efficiency depends upon the

Table 32.—Multipliers to Determine the Volume of Free Air Which, When Compressed, Is Equivalent in Effect to a Given Volume of Free Air at Sea Level

(Ingersoll-Rand Co. Copyright, 1906, by F. M. Hitchcock)

Altitude, ft.	Barometric Pressure		Gage Pressure (lb.)				
	In. of Mercury	Lb. per sq. in.	60	80	100	125	150
1,000	28.88	14.20	1.032	1.033	1.034	1.035	1.036

3,000	26.76	13.16	1.097	1.102	1.105	1.107	1.109
4,000	25.76	12.67	1.132	1.139	1.142	1.147	1.149
5,000	24.79	12.20	1.168	1.178	1.182	1.187	1.190
6,000	23.86	11.73	1.206	1.218	1.224	1.231	1.234
7,000	22.97	11.30	1.245	1.258	1.267	1.274	1.278
8,000	22.11	10.87	1.287	1.300	1.310	1.319	1.326
9,000	21.29	10.46	1.329	1.346	1.356	1.366	1.374
10,000	20.49	10.07	1.373	1.394	1.404	1.416	1.424

compression ratio of the first stage, which is determined by the cylinder ratio. Hence for a given cylinder ratio, the volumetric efficiency is practically unaffected by a change of altitude.

EFFECT OF ALTITUDE ON DRILL REQUIREMENTS.—Besides the change of volumetric efficiency with altitude of a compressor, the amount of air required by a drill or other air machine increases with the altitude, due to the greater volume of free air

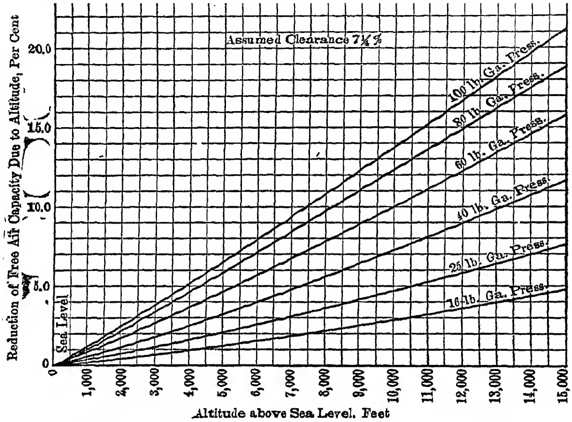

FIG. 8. Effect of Altitude on Compressor Capacity. (S. B. Redfield)

at local atmospheric conditions that will be forced into the drill cylinder under the greater number of compressions at the altitude. Thus there are two distinct effects: The drill requires more, and the single-stage compressor delivers less free air at a higher altitude.

Selection of Compressor for a given number of drills, pneumatic tools, hoisting engines or other class of pneumatic machines at an altitude: Add to the sea-level air consumption of the machines, the percentage increase they require at the altitude. Then select a compressor whose sea-level capacity is such that, when it is reduced by the percentage loss of volumetric efficiency for the altitude, shown by the curves in Fig. 8, its net delivery will at least equal the total air requirements. The diagram figures refer to air as measured by nozzle, not to piston displacement.

EXAMPLE.—Free air required by drills at 80 lb. per sq. in. at sea-level, is 250 cu. ft. per min. What is the compressor capacity for 6000 ft. altitude?

Increase of drill requirements (See Table 54) at 6000 ft. altitude, 20%. Free air required by drills, 250 × 1.20 = 300 cu. ft. per min. A certain single-stage compressor which delivers 340 cu. ft. per min. of free air at sea-level will do the work; the curves, Fig. 8, show a reduction of volumetric efficiency at 6000 ft. altitude and 80 lb. per sq. in. pressure, of about 7%. The net delivery at 6000 ft. altitude would then be 340 × 0.93 = 316 cu. ft. per min. This does not mean that the volumetric efficiency of the compressor is 93% but that its volumetric efficiency at 6000 ft. altitude is 93% of the volumetric efficiency at sea-level, as previously determined by sea-level test. This all depends on actual cylinder clearance. Fig. 8 is based on an average of 7 1/4% clearance.

Table 33.—Efficiency of Air Compression at Different Altitudes

E.—Required the volume of free air which when compressed to 100 lb. gage at 9000 ft. altitude will be equivalent to 1000 cu. ft. of free air at sea level; also the power developed in compressing this volume to 100 lb. gage in two-stage compression at this altitude. From Table 32, multiplier is 1.356. Equivalent free air = 1000 × 1.356 = 1356 cu. ft. From Table 34, power developed in compressing 1 cu. ft. of free air is 0.1473 Hp.; hence, 1356 × 0.1473 = 199.73 Hp.

3. SIZES AND TYPES OF AIR COMPRESSORS*

CLASSIFICATION OF AIR COMPRESSORS.—Air compressors may be classified according to the mode of drive as follows (Peele's Compressed Air Plant):

STEAM DRIVEN

Straight-line.
- Single-stage, double-acting: Direct-connected to steam engine. For long belting to steam engine. For short belting to steam engine.
- NOTE.—Two-stage, straight-line compressors for steam operation are built for high-pressure work only.
- Single-stage, double-acting, portable: Direct-connected to steam engine.

Duplex, small and medium capacity.
- Single-stage / Two-stage: Direct-connected to steam engine. belting to steam engine.

Duplex, large capacity: Direct-connected to steam engine.

Turbo-compressors: Direct-connected to steam turbine.

POWER DRIVEN

Vertical.
- Single-stage, single-acting, stationary: For long belting to line shaft, gasoline engine, or electric motor. For short belt drive.
- Duplex single-stage, single-acting portable: For short belt drive.

Straight-line.
- Single-stage, double-acting: For long belt drive. For short belt drive. For chain drive.
- NOTE.—Two-stage compressors of this type are built for high-pressure work only.
- Single-stage, double-acting, portable: For short belt drive. For chain drive.

Duplex, small and medium capacity.
- Single-stage / Two-stage: For long belt drive. For short belt drive.

Duplex, large capacity.
- Single-stage / Two-stage: For long belt drive. Direct-connected to electric motor, gasoline, gas, or oil engine, or water-wheel.

* Tables considerably abridged from the originals.

NOTE.—The following tables illustrate the sizes, capacities and horsepowers of standard type forms of compressors built by well-known makers. The compressors listed have been selected as typical of their respective classes, and there is no intention to discriminate against other good makes.

Table 35.—Straight-line Power-driven Compressors

Class ER-1. Air Pressure, 10 to 125 lb. per sq. in.

15	20	14	235	1189	40	14	2	4	7

The steam cylinders of the 6-, 8-, and 10-in. stroke N Class compressors have D-slide-valves; 12-in. stroke, double-port balanced valves. The air cylinders have "simplate" disc-valves. This company also builds duplex, single-stage compressors, Class O, driven by steam, belt or direct-connected electric motor, for pressures of 30 to 70 lb. per sq. in., and displacements from 1022 to 4424 cu. ft. per min.

Table 37.—Straight-line Steam-driven Compressors

Class FR-1. Air Pressures, 10 to 125 lb. per sq. in. Steam, 80 to 175 lb. per sq. in
(Ingersoll-Rand Co., New York)

14	12	250	1060	100	189	126	83
16	12	250	1390	60	188	126	83

These compressors are driven by a short belt. Five other sizes are built, for pressures of 30 to 50 lb. per sq. in.; also, 16 sizes of single-cylinder, belt-driven compressors (Type TB-S), with cylinders of the same dimensions, the displacements being one-half the above. This company also builds: A duplex, single-stage direct-motor driven compressor (Type SB-SD), with 18 × 14-in. cylinders; displacement, 1830 cu. ft. per min.; delivery pressure, 70 lb. Five sizes of the same type, with 20 × 14 to 28 × 16-in. cylinders; displacements, 2265 to 4520 cu. ft. per min.; delivery pressures, 50, 40 and 30 lb. per sq. in.; also several sizes of straight-line, single-stage, steam-driven compressors (Type STB-S).

The Ingersoll-Rand XPV class are built in four forms, all duplex; single- or two-stage air, with simple steam cylinders; single- or two-stage air, with cross-compound steam cylinders. Compressors of these general types are also built for belt and direct-connected motor drive.

Table 42.—Two-stage, Fuel Oil-driven Compressors, with Differential, Single-acting Air Cylinder

Class POC-2.
(Ingersoll-Rand Co., New York)

Displacement, cu. ft. per min.	Delivery Pressure, lb. per sq. in.*		Floor space				Height		Approx. Shipping Weight, lb.

24	14 1/2	16	1482–1852	243–307	12	2	10	0

In these compressors, the high-pressure cylinder is vertical, the low-pressure cylinder horizontal. They are also made in twin form (belt-driven or direct-connected), the capacity being then doubled. The Sullivan Machinery Co. also builds nine sizes of angle-compound compressors, with displacements of 313–2553 cu. ft. per min., direct-driven by Diesel engines.

20	29	18	24	165	3010	26	0	12	0

The Worthington Corp. also builds duplex, two-stage compressors, belt-driven or direct-connected to synchronous motors, with displacements from 350 to 3865 cu. ft. per min.

EFFICIENCIES OF STEAM- AND ELECTRICALLY-DRIVEN COMPRESSORS.—The measurements necessary for computing efficiencies are given in Figs. 9 and 10. Under the diagrams are the ratios of these measurements, resulting in the respective efficiency and performance measurement of a steam-driven and electrically-driven air compressor. (S. B. Redfield in Compressed Air Data, 1920.)

Notation.

E = Mechanical Efficiency.
E_M = Motor Efficiency.
E_V = Indicated Volumetric Efficiency.
E_A = Actual Volumetric Efficiency.
E_S = Slippage Efficiency.
E_I = Isothermal Compression Efficiency.

For Steam-Driven Compressors:

$E =$

$I.Hp._S$ per 1000 cu. ft. per min.

per ... ft. of air deliv'd $= \frac{\text{Lb. Steam per min.} \times 1000}{C}$

For Electrically-Driven Compressors:

$B.Hp._S$

$E.Hp._M$

p. per 100 cu. ft. of air delivered per min.

For Steam- and Electrically-driven Compressors:

E_V

$I.Hp._A$ per 100 cu. ft. per min. $= E_I$.

$I.Hp._A \times 100$

$I.Hp._A$ per 100 cu. ft. of air per minute.

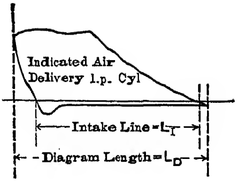
The following formulas (S. B. Redfield) exhibit in other forms the relations between the factors entering into the general expressions for compressor efficiencies. They are useful in dealing with different phases of air-compression problems.

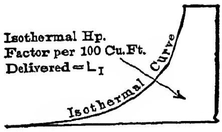
$$\frac{\text{Indicated Hp. of Air Cylinders}}{\text{Indicated Hp. of Steam Cylinders}} = \text{Mechanical efficiency, which is ordinarily } 90\%$$

to 95%. For a power-driven compressor, the denominator of this expression is the brake horsepower. The difference between the two indicated horsepowers is the power consumed in overcoming frictional resistance of the compressor.

$$\frac{\text{Length of Intake Line, Low-pressure Cyl.}}{\text{Total Length of Indicator Diagram}} = \text{Indicated volumetric efficiency.}$$

$$\frac{\text{Cu. Ft. of Free Air Delivered}}{\text{Cu. Ft. of Piston Displacement}} = \text{Actual volumetric efficiency, which usually is 65 to}$$





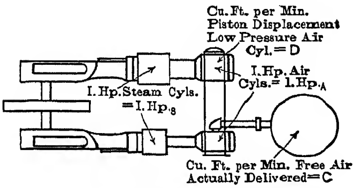


FIG. 9. Steam-driven Compressor

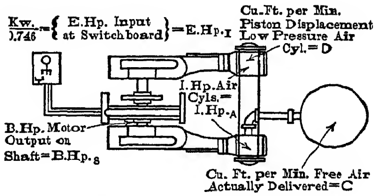

FIG. 10. Electrically-driven Compressor

This is useful for determining the actual output of air available for operating rock drills or other air-driven machines, but it does not necessarily connote economical performance of the compressor; that is, a compressor having high volumetric efficiency may have low total (overall) efficiency and *vice versa*.

$$\frac{\text{Actual Volumetric Efficiency}}{\text{Indicated Volumetric Efficiency}} = \text{Slippage Efficiency.}$$ This is the ratio of the volume of measured air delivered to the apparent volume shown by the indicator diagram, and is commonly 91 to 92%.

$$\frac{\text{Average Actual Work Done}}{\text{Maximum Capacity for Work}} = \text{Load Factor of Compressor,}$$ which otherwise may be defined as the ratio that the average power consumed bears to the maximum power during a stated period of time, as a day, month, or year.

Compression efficiency is the ratio that the theoretical power required to compress and deliver a given volume of air bears to the actual indicated horsepower developed in the air cylinder. According to the mode of compression, this is designated as Isothermal Compression Efficiency (usually 72 to 75%), or Adiabatic Compression Efficiency (say 80 to 85%). The terms Isothermal Factor and Adiabatic Factor are the theoretical horsepowers required to compress, isothermally or adiabatically, 100 cu. ft. of free air per minute to the designated pressure. For computations involving differences in barometric

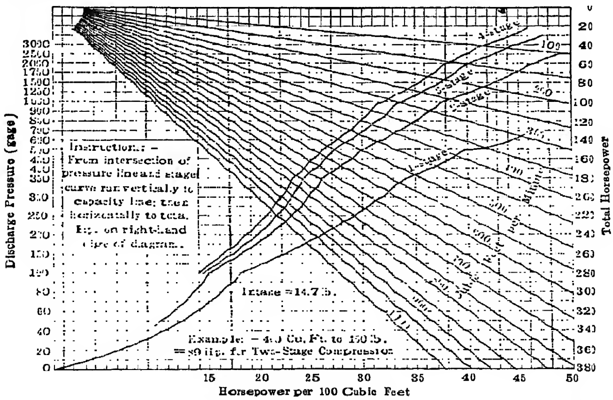

FIG. 11. Horsepower Chart for Adiabatic Compression, Perfect Intercooling. (S. B. Redfield)

pressure at altitudes it is customary to use the lower base, represented by the Isothermal Factor.

On the other hand, the Adiabatic Factor is most convenient for ordinary calculations of horsepower (see Tables 28, 29, and 30). Fig. 11 shows these relations graphically.

$$\frac{\text{Adiabatic Factor}}{\text{I.Hp. of steam cyl. per 100 cu. ft. free air per min.}} = \text{Overall or total adiabatic efficiency,}$$

which may also be expressed as the Adiabatic Compression Efficiency (see above) multiplied by the Mechanical Efficiency, and is roughly 75%. This is the most important, from the standpoint of the user of a compressor, because it is the ratio of the power represented by the volume of compressed air delivered to the power consumed in producing it. For a steam-driven compressor, the overall efficiency is as stated above; for a power-driven compressor, it is the Adiabatic Compression Efficiency × Mechanical Efficiency × Overall Efficiency of the prime mover (including belting).

STEAM CONSUMPTION IN AIR COMPRESSORS.—(O. S. Shantz, *Power*, Feb. 4, 1908).—Tables 47 and 48 show the steam required to compress 100 cu. ft. of free air to different gage pressures, in single- or in two-stage compression. They are based on the steam consumptions per I. Hp.-hr. at the head of each column. The computations are based on adiabatic compression in all the cylinders, with intercooling to atmospheric temperature in the case of two-stage compression, and a mechanical efficiency of 90%.

The tables are used as follows: A steam consumption per I. Hp. is assumed, according to the type of steam end of the compressor, steam pressure, cut-off, vacuum if condensing, etc. Under this assumed figure, on the line opposite the required air pressure are the pounds of steam per 100 cu. ft. of free air compressed. The accuracy of these tables in practice depends upon the correct assumption of the steam consumption per I. Hp. Where this is not exactly known the tables are, at best, only approximate. They are, however, useful for making comparisons of the fuel consumed by different types of compressors, thus showing the expected yearly saving by the use of, for instance, a compound as compared with a simple compressor. Thus, a straight-line compressor, with a steam consumption of 30 lb. per I.Hp., single-stage compression to 100 lb. per sq. in. gage, required 9.9 lb. of steam per 100 cu. ft. of free air. A duplex compressor, at the same steam consumption, but with two-stage air cylinders, requires 8.42 lb. of steam. A stage compressor with compound steam cylinders, non-condensing, with 26 lb. steam rating requires 7.3 lb. of steam, while a high class Corliss two-stage compound condensing compressor, using steam at high pressure, having a water rate of 17 lb. (including condenser), requires only 4.77 lb. of steam.

Table 47.—Steam Consumption of Air Compressors—Single-stage Compression

Air Gage Pressure	Steam per I.Hp.-hr., lb.

COST OF COMPRESSING AIR BY DIFFERENT DRIVES. (H. V. Conrad.)—In considering the purchase of a small compressor, say 50 to 100 Hp., it is desirable to consider the different sources of power and cost of fuel. Data in Tables 49, 50 and 51 give comparisons where the compressor is driven by: *a*. Gasoline engine, direct-connected or belt-driven; *b*. Steam engine, direct-connected or belt-driven; *c*. Electric motor, direct-connected or belt-driven.

In using the tables, figures suitable for local conditions must be assumed, after first

Table 49.—Cost of Gasoline, in Cents, to Compress and Deliver 100 Cu. Ft. of Free Air to 90 lb. per Sq. In., Gage

Gasoline consumption taken as one pint per brake Hp.-hour

Brake Hp. to Deliver 100 cu. ft. Free Air per min.	Price of Gasoline per Gallon, Cents							
	8	9	10	11	12	13	14	15
16	0.266	0.300	0.333	0.366	0.400	0.433	0.466	0.500
18	.300	.337	.375	.413	.450	.487	.525	.562
20	.333	.375	.416	.458	.500	.542	.584	.626
22	.366	.412	.458	.504	.550	.595	.642	.687
24	.400	.450	.500	.550	.600	.650	.700	.750
26	.433	.488	.542	.596	.650	.705	.759	.813
28	.466	.525	.583	.642	.700	.758	.816	.875
30	.500	.563	.625	.688	.750	.813	.875	.938

EXAMPLE.—If it requires 22 B.Hp. to deliver 100 cu. ft., free air per min. at 90 lb. pressure with gasoline at 22 cts. per gal., the gasoline cost per 100 cu. ft. of free air is 0.504 × 2 = 1.08 cts.

Table 50.—Cost of Coal to Compress and Deliver 100 Cu. Ft. Free Air.

Air compressed to 90 lb. per sq. in., gage. Cost of coal taken at $1.00 per ton of 2000 lb.

	Steam Required by Engine, lb. per Hp.-hr									
	24	26	28	30	32	34	36	38	40	42
	Coal per lb. per Hp.-hr. when Boiler Evaporates 7 lb. Water per lb. of Coal									
	3.43	3.714	4.00	4.286	4.571	4.757	5.143	5.428	5.714	6.00
Brake Hp. to Deliver 100 cu. ft. Free Air per min.	Cost of Coal per Hp.-hr. at $1.00 per Ton, Fractions of Cent									
	0.1715	0.1857	0.200	0.2143	0.2285	0.2378	0.2571	0.2714	0.2857	0.300
	Cost of Coal per 100 cu. ft. Free Air, Fractions of Cent									
16	0.0457	0.0495	0.0533	0.0572	0.0610	0.0634	0.0686	0.0724	0.0762	0.08
18	.0514	.0557	.06	.0643	.0686	.0714	.0772	.0814	.0857	.09
20	.057	.0619	.0667	.0714	.0762	.0793	.0857	.0904	.0952	.10
22	.0627	.0681	.0733	.0785	.0838	.0872	.0943	.0995	.1047	.11
24	.0684	.0743	.08	.0857	.0914	.0951	.1029	.1085	.1142	.12
26	.0741	.0805	.0866	.0929	.099	.103	.1114	.1175	.1238	.13
28	.0798	.0867	.0933	.10	.1066	.1109	.12	.1266	.1334	.14
30	.0855	.0929	.10	.1071	.1142	.1189	.1285	.1357	.1429	.15

Example.—If it requires 22 B.Hp. to deliver 100 cu. ft. free air per min. at 90 lb., and the engine requires 34 lb. of steam per Hp.-hr., and the boiler evaporates 7 lb. of water per lb. of coal, with coal at $6 per ton, the coal cost per 100 cu. ft. of free air is 0.087 × 6 = 0.5232 cent.

Table 51.—Cost of Electric Current, in Cents, to Compress and Deliver 100 Cu. Ft. of Free Air to 90 Lb. per Sq. In. Gage

Brake Hp. to Deliver 100 cu. ft Free Air per min.	Price of Electric Current per kw.-hr., Cents								
	1 0	1.5	2.0	2.5	3.0	3.5	4 0	4.5	5.0
	Price per Hp.-hr., Cents								
	0.75	1.125	1.5	1 875	2.25	2 625	3.0	3.375	3.75
16	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
18	.225	.337	.45	.562	.675	.787	.9	1.012	1.125
20	.25	.375	.5	.625	.75	.875	1.0	1.125	1.25
22	.275	.412	.55	.687	.825	.962	1.1	1.237	1.375
24	.3	.45	.6	.75	.9	1.05	1.2	1.35	1.5
26	.325	.487	.65	.812	.975	1.137	1.3	1.46	1.625
28	.35	.525	.7	.875	1.05	1.225	1.4	1.575	1.75
30	.375	.562	.75	.937	1.125	1 312	1.5	1.687	1.875

EXAMPLE.—If it requires 22 B.Hp. to deliver 100 cu. ft. of free air per min. at 90 lb. pressure, with electric current at 4 cts. per Kw.-hr. the cost of electric current per 100 cu. ft. free air is 1.1 cts

determining the horsepower required to compress and deliver 100 cu. ft. of free air per minute, and assuming that the mechanical efficiency of all the machines is about the same.

In Table 50 the steam consumption must be approximately determined. In the example, it is taken at 34 lb. per Hp.-hr. The boiler evaporation is given as 7 lb. of water per pound of coal, and any variation from this performance should appear in the calculations.

COST OF COMPRESSORS.—Previous to requesting bids from compressor builders, preliminary estimates often are made by engineers or managers, on the basis of ascertained local conditions. In this connection, Table 52 will be useful. The costs cited

Table 52.—Cost of Compressors per Cubic Feet of Free Air per Min., Compressed to 100 Pounds per Square Inch.

(Including accessories for standard equipment, Jan. 1, 1930.)

Type of Compressor	Capacity Range, cu. ft. of Free Air per min.	Cost per cu. ft. of Free Air
Straight-line, steam-driven	67– 386	$15.90–$
Straight-line, belt-driven	44– 528	6.25– 2.85
Vertical, single-cylinder, belt-driven	7.3– 44	7.85– 4.50
Vertical duplex, direct electric-driven	58– 316	11.20– 6.80
Cross-compound, 2-stage air, duplex steam, Meyer valve	246–1723	11.10– 5.95
Cross-compound, 2-stage air, duplex steam, piston valve	246–3026	11.10– 5.75
Cross-compound, 2-stage, direct electric-driven	340–3864	9.50– 4.90
Cross-compound, 2-stage, belt-driven	348–1575	5.00– 3.55
Horizontal, single-acting, 2-stage, driven by horizontal oil engine	603– 895	15.10–14.80
Vertical, single-acting, 2-stage, driven by horizontal oil engine	354	15.50
Horizontal, double-acting, duplex or 2-stage, driven by vertical, duplex, single-acting, 4-cycle gas engine *	143–1938	34.00–31.00
Portable, truck-mounted, vertical, duplex gasoline-driven	66– 310	15.90–11.30
Mine-car type, vertical, duplex, electric-driven	70– 250	18.00–12.00

* The high cost of compressors driven by gas engines is offset in part by the cheapness of fuel gas.

therein are as of Jan. 1, 1930, apply to types of compressors in general use and of the capacities (sizes) stated for each type, and include all accessories generally considered

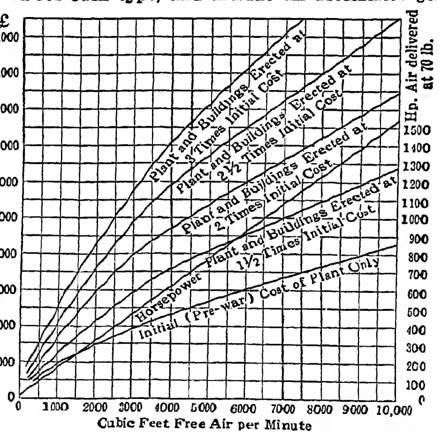

Fig. 12. Approximate Cost of Compressed Air Installations; 2-stage, with Compound Non-condensing Steam Cylinders; Air Pressure, 70 lb. (Daw, *Comp. Air Power*)

necessary for standard equipment, except such items as special governors, regulators, automatic water valves, etc.

Fig. 12 will assist in estimating approximate costs of completely installed plants (pre-war figures, 1914). Further aid generally is obtainable for cost figures existing in the great mass of engineering literature. On finding an installation similar to that desired, the unit costs applying to it can be adjusted to accord roughly with present-day

costs, by making the proper percentage increase or decrease. The results may be checked by referring to Table 52.

In asking bids from makers, the following points must be covered: Kind of service (as for drills, pumps, hoists, etc.), working pressure and volume of air required per minute, altitude above sea-level at which compressor will be used, general type of plant desired, whether steam- or belt-driven, kind and cost of fuel, electric current or water power available, and local transport facilities.

4. USES OF COMPRESSED AIR

CONSUMPTION OF AIR BY ROCK DRILLS depends on the size of drill and its physical condition, air pressure, character of rock, and the proportion of the total time actually occupied in drilling.

In hard rock, the drilling speed is slower than in soft, so that the machine makes longer continuous runs; hence, less total time is consumed in shifting and setting up for a succession of holes in hard rock, and the air consumption per unit of time is greater.

Table 53.—Cubic Feet of Free Air per Minute Consumed by One Drill at Sea Level

Gage Pressure, lb. per sq in.	Cylinder Diameter of Drills, in.												
	2	2 1/4	2 1/2	2 3/4	3	3 1/8	3 3/16	3 1/4	3 1/2	3 5/8	4 1/4	5	5 1/2
60	50	60	68	82	90	95	97	100	108	113	130	150	164
70	56	68	77	93	102	108	110	113	124	129	147	170	181
80	63	76	86	104	114	120	123	127	131	143	164	190	207
90	70	84	95	115	126	133	136	141	152	159	182	210	230
100	77	92	104	126	138	146	149	154	166	174	199	240	252

The compressor capacity required for one drill is greater than the average for a number of drills, because the delays to which each drill is subject, for setting up and shifting, changing bits, and for stoppages, make it improbable that all will be in simultaneous operation. See Peele's Compressed Air Plant, 5th Ed., pp. 384–392.

In soft rock, though the drilling speed is greater, there are apt to be more delays, due to "rifling" of the hole and sticking ("fitchering") of the bit; also, longer delays for piston than for hammer drills.

The figures in Table 53 are for average conditions, in moderately hard rock. For very hard rock ground and high air pressure, it is often advisable to provide, say, 20 to 25% additional compressor capacity. No allowance is made in the table for transmission losses due to pipe friction and leakage.

Example.—Required the amount of free air for operating 30 5-in. drills at 9000 ft. altitude, and gage pressure of 80 lb. per sq. in.

From Table 53, one 5-in. drill requires 190 cu. ft. of free air per min. From Table 54, the factor for 30 drills at 9000 ft. altitude is 20.38: $20.38 \times 190 = 3872$ cu. ft. free air per min. = displacement of a compressor for the above outfit under average conditions, to which must be added pipe line losses.

The size of compressor in cu. ft., required for any number of drills of all types may be found from the formula $S = M \times A \times P$, where S = size of compressor required (cu. ft.); M = a multiplier obtained from the curve, Fig. 13; A = ($5 \times$ number of piston drills $+ 4 \times$ number of leyners $+ 3 \times$ number of jackhamers and stopers); P = gage pressure at compressor, lb. per sq. in.

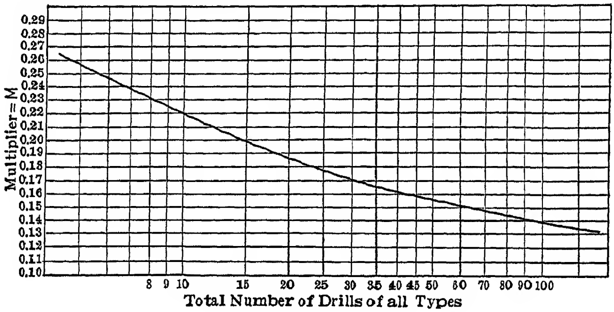

Fig. 13. Values of M

Example.—What size of compressor is required to operate one 3-in. piston drill, 3 leyners, 10 stopers and 6 jackhamers at 80 lb. per sq. in. pressure? Total number of drills = 20; from Fig. 13, for 20 drills, $M = 1.86$.

1 piston drill $\times 5 = 5$; 3 leyners $\times 4 = 12$; 10 stopers $\times 3 = 30$; 6 jackhamers $\times 3 = 18$; Total $= 65 = A$. Then $M \times A \times P = 0.186 \times 65 \times 80 = 970$, or, say 1000 cu. ft. compressor capacity.

AIR REQUIRED FOR HOISTING.—Table 55 includes the power required to hoist the skip and rope and to overcome friction. It assumes that 20% of the power is consumed in friction, that the skip weighs one-half as much as its contents, and that the traction on a horizontal mine track is 30 lb. per ton. It also provides for 500 ft. of wire rope. The air consumption is based on the assumption that a plain slide-valve engine is used, loaded to nearly full capacity. In estimating the consumption of air per hour, allowance should be made for the time the engine stands idle. If the compressor is large, doing other work also, its capacity should be based on the hourly consumption, in which case allowance is made for the time the hoist stands idle. If, however, the compressor drives the hoist alone, the hoist should be considered as running continuously. For a balanced hoist use only the unbalanced load in applying this rule. If the engine is not loaded to its full capacity, the air being throttled, it requires more air for the same work. Decreasing hoisting speed will diminish the power developed and the air consumed, but as the hoisting time is thereby lengthened, the air consumed per hoist remains unchanged. Increased speed will give a corresponding result.

COMPRESSED-AIR TABLE FOR HOISTING-ENGINES.—(Ingersoll-Rand Co. 1924.)—Table 56 gives the approximate volume of free air required for operating hoisting-engines, the air pressure at the engine being 60 lb. gage. There are so many variable conditions in the operation of hoisting-engines that accurate computations can be made only when fixed data are given. In the table, the engine is assumed to run one-half of the time for hoisting, while the compressor runs continuously. If the engine runs less than one-half the time, the volume of air required is proportionately less. The table is computed for maximum loads, which vary widely. Due to the intermittent work of a hoisting-engine, the parts resume their normal temperature between hoists, and there is little probability of freezing the exhaust-passages.

OPERATION OF MINE PUMPS BY COMPRESSED AIR.—The advantages of compressed air over steam for mine pumps are: Absence of condensation and radiation losses in pipe lines; high efficiency of compressed-air transmission; ease of disposal of exhaust; absence of danger from broken pipes. The disadvantage is that, at a given initial pressure without reheating, a cylinder full of air develops less power than steam. The power end of the pump should be designed for the use of air, with small clearances and proper proportions of air and water ends, for the head under which the pump is to operate. Wm. Cox (*Comp. Air Mag.*, Feb., 1899) states the relations of simple or single-cylinder pumps to be $A/W = {}^1/_2 h/p$, where A = area of air cylinder, sq. in.; W = area of water cylinder, sq. in.; h = head, ft.; and p = air pressure, lb. per sq. in. The volume V of free air in cu. ft. per min. to operate a single-cylinder pump, working without cut-off is

$$V = 0.093W_2 /(hG \div P),$$

where W_2 = volume of 1 cu. ft. of free air corresponding to 1 cu. ft. of air at pressure P; G = gal. of water per min.; P = gage pressure of air, lb. per sq. in.; and h = head, ft. This formula is based on a piston speed of 100 ft. per min., and 15% is added to the volume of air to cover losses. The useful work and efficiency of a pump using air at full pressure is greater at low air pressures than at high. Hence, as high-pressure air is required for drills, etc., and as the air for pumps is drawn from the same main, the air must either be wire-drawn into the pumps, or a reducing valve be inserted between the pump and main. Wire-drawing causes a low efficiency in the pump. If a reducing valve is used, the increase of volume will be accompanied by a drop in temperature, so that the full value of the increase is not realized. Part of the lost heat may be regained by friction, and from external sources. Efficiency may be increased by underground receivers for the expanded air before it passes to the pump. If the receiver be of ample size, the air will regain nearly its normal temperature, the entrained moisture will be deposited and freezing troubles avoided. By compounding the pumps, the efficiency may be increased to about

25%. In simple pumps it ranges from 7 to 16%. For further information on this subject see Peele's Compressed-Air Plant, 5th ed., 1923.

free air. Pressure required on the pump is in the column directly opposite.

EXAMPLE.—The ratio between cylinders being 2 to 1, it is required to pump 100 gal. to a height of 250 ft. Opposite 250 at ratio 2 to 1, is 2.11; 2.11 × 100 = 211 cu. ft. free air. Pressure required, 34.38 lb. delivered at pump piston.

5. REHEATING COMPRESSED AIR

INCREASE OF PRESSURE due to reheating of compressed air is shown by the chart Fig. 14, the volume being constant. The air is assumed to be heated from initial temperatures of 0°, 32°, 60°, and 100° F.

INCREASE OF VOLUME due to reheating is shown by the chart, Fig. 15. The air is assumed to be heated from the initial temperatures of 0°, 32°, 60°, and 100° F., the pressure remaining constant. The relative volume at any temperature is given by the height of the vertical line corresponding to that temperature, the height from *AB* to *CD* representing one volume, and each horizontal line above *CD* indicating successively an added one-tenth volume. The original volume is doubled at the line *EF*. Figures below *AB* indicate the sensible temperatures; those above *EF* indicate the corresponding absolute temperatures.

TEMPERATURE OF INTAKE AIR, for economy, should be as low as possible. Hence, it is best taken, not from the warm engine room, but from outside of the building, preferably at a point shielded from direct rays of the sun, and free from dust. For every 5° F. lower temperature, the gain is approximately 1%.

Table 59.—Effect of Intake Temperature on Efficiency and Capacity of Compressors

Unit Capacity and Efficiency Assumed at 60° F.

Initial Temp.		Relative Capacities and Efficiencies	Initial Temp.		Relative Capacities and Efficiencies	Initial Temp.		Relative Capacities and Efficiencies
Deg. F.	Deg. Abs.		Deg. F.	Deg. Abs.		Deg. F.	Deg. Abs.

−10	451	1.155	50	511	1.020	120	581	.896
0	461	1.13	60	521	1.000	130	591	.880
10	471	1.104	70	531	0.980	140	601	.866
20	481	1.083	80	541	.961	150	611	.852
30	491	1.061	90	551	.944	160	621	.838
32	493	1.058	100	561	.928			

The saving shown in Table 59 is obtained at practically no cost. The area of the intake duct should be at least half the area of the compressor cylinder, and to reduce frictional resistance it is well to increase the area by 1 sq. in. for every 10 ft. in length. Tile pipe is a good material for intake ducts, due to its low conductivity.

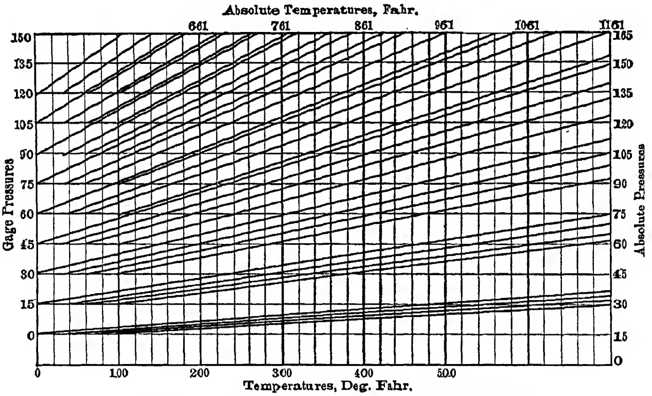

FIG. 14. Increase of Pressure Due to Reheating

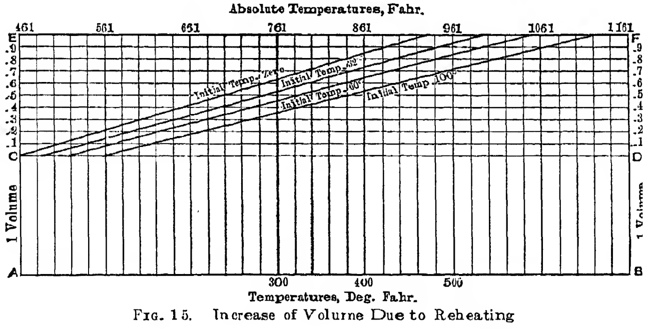

FIG. 15. Increase of Volume Due to Reheating

AFTER-COOLING.—By passing the air from the compressor through an after-cooler and reducing its temperature approximately to normal, much of the moisture will be condensed and may be removed before it can enter the pipe line, since compressed air has less capacity for moisture than air at atmospheric pressure. An after-cooler gives better results with a moderate quantity of cold water, rather than with an unlimited supply at higher temperature.

With the amounts of water given in Table 61 for ordinary working conditions, the temperature of the air leaving the inter-cooler or after-cooler should be within 20° F. of the temperature of the water used, when the cooler takes air from a two-stage compressor (100 lb. per sq. in. discharge pressure), and the initial water temperature is about 70° F.

Table 61.—Cooling Water Required for After-coolers, Inter-coolers and Cylinder Jackets
Gal. per 100 cu. ft. of free air for different water temperatures

SIZE OF AIR RECEIVER FOR GIVEN CAPACITY OF AIR COMPRESSOR.—1. Determine the maximum capacity of the compressor in free air per min., or piston displacement per min. 2. Compute the volume occupied by this air at the working pressure; this is the required volume of the receiver.

This computation gives approximately the minimum size of receiver necessary; a larger size is preferable. The receiver should be sufficiently large to prevent fluctutations in pressure and to retain the air long enough for it to cool and deposit part of its moisture.

6. CENTRIFUGAL COMPRESSORS

The theory underlying the design and operation of turbo- or centrifugal compressors, and their fundamental mechanical features (shape and number of impellers in series, and number of stages), are the same as for centrifugal fans and pumps. See p. 1–55. The inlets may be single or double, and axial or radial, according as the air or gas enters parallel to or at right angles to the shaft on which the impellers are mounted; for large volumes, they are generally axial. To minimize eddies, the air issuing from the impellers passes into the casing in streams between stationary vanes or shrouds. Means are provided to prevent leakage of air from one impeller or stage to another, or to the

atmosphere. Rotative speeds are generally from 3000 to 6000 r.p.m.; discharge velocity of the air, rarely less than 300 ft. per sec. In passing from each impeller into the discharge passages leading to the next in the series, the air velocity is converted into head or pressure, each impeller adding an increment of say $2\,1/2$ to 6 lb. per sq. in.

Centrifugal compressors designed for pressures up to about 5 lb. per sq. in. are called blowers, and have a single impeller; for higher pressures a series of impellers is used. For pressures above, say, 30 or 35 lb. per sq. in., stage compression is customary, several series of impellers being mounted on the same driving shaft, each series having its own casing. The last impeller of one series delivers air to the first of the next series. By four stages, the pressure may be built up to 150 lb. per sq. in. or more. Multi-stage compressors have intercoolers between the stages, and water-jackets for the individual impellers. In the first impellers, where the pressure is low, the temperature rises rapidly, notwithstanding the water-jackets, but, as the density of the air increases, cooling becomes more effective, with good isothermal efficiency. The volume of cooling water, at 70° F., is roughly 165 gal. per min. per 1000 Hp., sometimes estimated at 3000 gal. per hr. per 1000 cu. ft. of free air compressed per min. to 100 lb. per sq. in.

CAPACITY ranges from small units of 250–700 cu. ft. per min. up to about 60,000 cu. ft. of free air per min.; delivery pressures are, roughly, 1 to 35 lb. per sq. in. for cupola and blast-furnace blowers, to 100 to 170 lb. per sq. in. for multi-stage compressors. A number of high-pressure units, of 12,000 to 13,000 Hp., are used at central distributing plants in the South African gold fields (see Peele's Compressed Air Plant, 5th ed., pp. 97, 506–511). In general, compressors delivering 5000 to 12,000 cu. ft. of free air per min. at pressures of 85 to 120 lb. per sq. in. gage, should run 3500–3800 r.p.m.; those for, say, 2500 cu. ft. per min. at 70 to 85 lb. per sq. in., and for 1750 cu. ft. per min. at 60 lb. per sq. in. should run at 4200–4500 r.p.m.

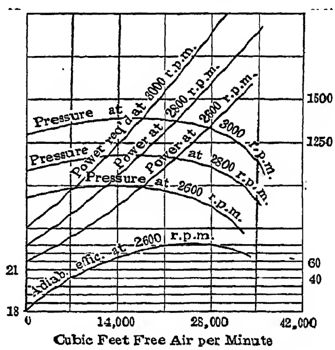

Fig. 16. Performance of 3-stage Centrifugal Compressor

Among the principal makers of centrifugal compressors are Ingersoll-Rand Co., N. Y. City; General Electric Co., Schenectady, N. Y.; Westinghouse Electric, Thomson-Houston and General Electric Cos., Great Britain; and Sulzer Bros., Winterthur, Switzerland. An instruction book of 60 pp., issued by the General Electric Co., Schenectady, N. Y., gives details of construction of multi-stage compressors, with directions for installation and operation.

APPLICATIONS.—1. Power transmission in general. 2. For blast- and other furnaces. When air must be supplied to these in uniform volume against a variable resistance, the speed of rotation is adjusted to air demand by a special governor, controlled by the varying air velocity in the compressor inlet. The weight of oxygen supplied to the furnace is thus quite accurately regulated. A nearly constant pressure also can be maintained, even with large fluctuations in volume of air used. For example, a compressor running normally at 4600 r.p.m., and 35 lb. per sq. in. pressure, showed only 2 to 3 lb. variation for outputs ranging from 1500 to 6000 cu. ft. of free air per min. Metallurgical service requires no higher pressures than 35 to 40 lb. per sq. in. 3. Exhauster service, for conveying comminuted materials, as cement, sawdust, ash, products of the flotation ore concentration process, etc. 4. Agitation of liquids, as in oil refining and treatment of sewage at disposal plants. 5. Gas making, ventilating, cooling and sundry manufacturing uses. 6. A low-pressure centrifugal may be used to deliver air at, say, 30 lb. per sq. in. to a high-pressure reciprocating compressor. This reduces about 60% the volume handled by the latter, decreases its size and increases the total efficiency.

ADVANTAGES are, for the larger units, lower initial and maintenance costs than for a reciprocating compressor of equal capacity, less floor space, freedom from vibration, non-pulsating discharge, good efficiency under quite wide load variation. Furthermore, as there is no internal lubrication, the discharge air is free from oil vapors, often a desirable condition. For the same reason, there can be no explosions in receivers or piping from mixtures of air and oil vapor, which may occur with reciprocating compressors.

Except for very low pressures, it is not generally advisable, in point of first cost, to adopt centrifugal compressors for capacities smaller than 2200–2500 cu. ft. of free air

per min. Also, except for very large units, like those of the South African plants already cited, reciprocating compressors are best for air pressures above, say, 70–85 lb. per sq. in. The air end of centrifugal compressors delivering more than 6000 cu. ft. of free air per min. should work under full load at 70 to 80% efficiency; those between 3000 and 6000 cu. ft., 65 to 70% efficiency at full load, and below 50% at half load. In general, the efficiency increases with the number of stages. Fig. 16 shows the performance of a three-stage compressor at different speeds.

COMPRESSOR CONSTANT, K may be expressed as $K = QN^2 \div \sqrt{p^3}$, where Q and p are, respectively, the volume and mean effective pressure of the air, and N = r.p.m. For different combinations of Q and p, the efficiency is practically unaltered. Compressors having the same constant are said to be *similar;* that is, their impeller and discharge vane angles are respectively equal, while the linear dimensions of these parts are in the same ratio as the impeller diameters. At the same speed, the volumes delivered by similar compressors vary as the cubes, the pressures as the squares, and the shaft horsepowers as the fifth powers of their diameters. At the same r.p.m. and constant pressure, the volume and horsepower vary as the square of the impeller diameter. In making tests, the coefficients found from observations are plotted as characteristic curves, like those of centrifugal pumps (see p. 2–80), from which the power, pressure, and efficiencies are computed for any given volume.

The power required by a centrifugal compressor, at from about one-half load to 25% overload, varies approximately with the load. If the demand for air ceases while the compressor is at full speed, the casing will heat, but no other hurtful strains will occur. The theoretical Hp. to compress adiabatically and deliver 100 cu. ft. of free air per min. is

$$\text{Hp.} = 1.511p_1\left[\left(\frac{p_2}{p_1}\right)^{0.29} - 1\right] \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [16]$$

where p_1 and p_2 are initial and delivery pressures, lb. per sq. in. absolute (see Theory of Air Compression, p. 1–29). For the largest range of pressures likely to occur in practice, the ratios of isothermal to adiabatic work, from which approximate actual horsepower for a given delivery pressure can be estimated, are as follows (L. C. Lowenstein):

p_2/p_1..........	1.5	2.0	2.5	3	4	5	6	7	8	9	10
Isoth. ÷ Adiab.	0.94	.904	.875	.85	.812	.784	.763	.744	.728	.715	.703

DRIVING UNIT.—This is generally a direct-connected, high-pressure or mixed-pressure steam turbine of two or more stages, or occasionally, an electric motor. Gearing is sometimes used for small units. A mixed-pressure turbine is designed to carry its rated load with either live or low-pressure (exhaust) steam, or a combination of the two. Its operation is determined by the available volume of exhaust-steam, through control of a special governor. Sometimes, live steam is used in the first stage of the turbine, low-pressure steam, as from the exhaust of another engine, in the second stage. When the steam supply is used also for a heating system, subject to large fluctuations, the bleeder type of turbine is advisable. Boiler steam is expanded in the turbine to a predetermined pressure, at which part of the steam passes to the heating system, the remainder expanding further in the lower stages. A bleeder turbine can work at high pressure, if no steam is wanted for heating. According to a test on a 1000-Hp. mixed-pressure turbine, driving a compressor delivering 4400 cu. ft. of free air per min., compressed to 99 lb. per sq. in., there were used per 100 cu. ft. free air, 5.05 lb. of live steam at 85 lb. per sq. in., and 7.98 lb. exhaust steam, entering at 15.6 lb. per sq. in. and discharged at 1.14 lb. per sq. in.

INFORMATION REQUIRED BY MAKERS for submitting specifications and estimates includes:

For Compressor: Character of service, *i.e.*, for compressor or blower; nature of gas, if other than air; whether it is saturated, dry, or corrosive; kind of service; altitude of installation; intake temperature and volume (cu. ft. per min.); normal, minimum and maximum discharge pressure; hand or automatic control; if automatic, whether regulation is for constant volume or pressure.

For Driving Unit: If turbine, initial steam pressure and temperature; exhaust and back pressure; if of bleeder type, pounds of steam bled per hour, with its corresponding pressure. If electric motor, type, as induction, synchronous or direct-current; voltage, phase and cycles; squirrel-cage or slip ring type; starting equipment, manual or automatic.

7. HYDRAULIC AIR COMPRESSION

HYDRAULIC AIR COMPRESSOR.—When air in small bubbles is intimately mixed with water, the water breaks into foam, through which the bubbles tend to rise and escape. But if the mixed air and water be drawn downward by a strong falling current, as in a vertical pipe, the air is compressed. Then if, after reaching the depth and head

of water-column necessary to produce the compression desired, the direction of flow be changed and the velocity diminished, the bubbles of compressed air will be liberated and may be collected in a suitable chamber. The air pressure in this chamber corresponds to the effective head of water, that is, its depth below the level at the outflow. As the bubbles are thoroughly disseminated through the water during its descent, the total cooling surface is large and isothermal compression results. The moisture-carrying capacity of the air is therefore smaller than if it were compressed adiabatically. During compression the percentage of moisture in each globule of air increases until the point of saturation is reached; on further compression, the excess moisture is deposited, so that when re-expanded the air is relatively dry.

A typical apparatus consists of a vertical down-flow or compressing pipe, having a receiving tank at the top and a separating chamber at the bottom. Partly immersed in the receiving tank is a headpiece, containing a number of small vertical pipes, open to the air at the top and closed at the bottom. Inserted in these are numerous short horizontal tubes, directed towards the middle of the down-flow pipe. As the entering water passes among the horizontal tubes, air is entrained, carried as bubbles into the down-flow pipe and is thus compressed. On reaching the separating chamber at the bottom, the mixture of air and water is deflected radially outward by a cone and horizontal baffle plate, and, as velocity of flow decreases, the compressed air is liberated and accumulates in a receiving or storage chamber, from which it is drawn off as required. Finally, the water is discharged into an ascending pipe to a tail-race; the effective compressing head being equal to the difference in level between the water in the air storage chamber and that in the tailrace.

A number of these plants have been installed by the Taylor Hydraulic Air Compressing Co., Montreal. The first was at the Magog Cotton Mills, Prov. Quebec (1896). The principal dimensions are: Supply penstock, 60 in. diam.; supply tank, 8 ft. diam., 10 ft. high; air inlets (feeding numerous small tubes), 34 2-in. pipes; down-flow pipe 44 in. diam., increasing at lower end to 60 in. diam.; separating chamber 16 ft. diam.; total depth of shaft below normal level of head water, about 150 ft.; motive head, between water levels in receiving tank and tailrace, about 22 ft.; air discharge pipe, 7 in. diam.

Table 63.—Tests of Hydraulic Air Compressors at Magog Cotton Mills *

Test No.	1	3	4	5	7	8	10
Flow of water, cu. ft. per min.	3772.	3628.	4066.	4292.	4408.	4700.	5058.
Available head in ft.	20.54	20.00	20.35	19.51	19.93	19.31	18.75

Moisture in comp. air, percent of saturation	51.5	44.	38.5	35.	29.	31.2	30.

* Tests 1, 4, and 7 were made with the original air inlets; 1, 5, 8 and 10 with the inlets increased by 15 3/4-in. pipes, and 3, 6, 9 and 11 with the inlets increased by 30 3/4-in. pipes. Tests 2, 6, 9 and 11 are omitted here. They gave, respectively, 55.5, 61.3, 62, and 55.4% efficiency.

Tests: (1) Three tests were made at different rates of flow of water; (2) Four tests at different rates of flow, the air inlet tubes being increased by 30 3/4-in. pipes; (3) Four tests, with the inlet tubes being increased by 15 3/4-in. pipes (see Table 63).

The water was measured by a weir, and the compressed air by meters.

Test 1, with flow about 3800 cu. ft. per min., showed a decided advantage by the use of 30 3/4-in. extra air inlet pipes. Test 5 shows, when flow of water is about 4200 cu. ft. per min., that the economy is highest when only 15 extra air tubes are employed. Tests 8 and 9 show, when flow is about 4600 cu. ft. per min., that there is no advantage in increasing the air-inlet area. Tests 10 and 11 show that a flow of 5000 or more cu. ft. of water is in excess of the capacity of the plant.

Summary: (1) The most economical rate of flow of water in this installation is about 4300 cu. ft. per min. (2) This plant has shown an efficiency of 70.7% under such a flow. (3) The compressed air contains only from 30 to 20% as much moisture as does the atmosphere. (4) The air is compressed at the temperature of the water.

Using an old Corliss engine, without changes in the valve gear, there was recovered 81 Hp. This would represent a total efficiency of work recovered from the falling water, of 51.2%. When the compressed air was preheated to 267° F. before being used in the engine, 111 Hp. was recovered,

using 115 lb. of coke per hour, which would equal about 23 Hp. The efficiency of work recovered from the falling water and the fuel burned would be, therefore, about 61 1/2%. Other hydraulic air-compressor plants are:

	Peterboro, Ont.	Norwich, Conn.	Cascade Range, Wash.	Victoria Mine, Mich.	Cobalt, Ont.
Head of water..........	14 ft.	18 1/2 ft.	45 ft.	70.5 ft.	54 ft.
Gage pressure...........	25 lb.	85 lb.	85 lb.	113 lb.	120 lb.
Diam. of shaft..........	42 in.	24 ft.	....	....	....
Diam. compressor pipe...	18 ft.	13 ft.	3 ft.	5 ft.	8 1/2 ft.
Depth below tailrace.....	64 ft.	215 ft.	....	270 ft.	276 ft.
Horsepower.............	....	1365	200	4000	5500

In the Cascade Range plant there is no shaft, as the apparatus is constructed against the vertical walls of a canyon. The upflow pipe is 4 ft. 9 in. diam.

A description of the Norwich plant is given by J. Herbert Shedd (*Compressed Air*, April, 1906). The shaft, 24 ft. diam., is enlarged at the bottom into a chamber 52 ft. diam., leading to an air reservoir 100 ft. long, 18 ft. wide and 15 to 20 ft. high. The downflow pipe is 14 ft. diam. A 16-in. main conveys the air 4 miles to Norwich, where it is used in engines in several establishments.

FANS AND BLOWERS *

By Robert Thurston Kent

1. CENTRIFUGAL

The essential parts of a centrifugal fan are: A rotating wheel or impeller to set up centrifugal action in the air or gas to be moved; a housing, usually spiral, to convert part of the kinetic energy in the air to static or potential energy to overcome friction, and also to connect the fan outlet to the discharge duct or chamber; an inlet connecting the wheel inlet with the duct or chamber being evacuated, and also directing the air into the wheel; a shaft and bearings to carry the wheel, and means to rotate the shaft.

TYPES OF FANS.—Radial Fans, the blades lying on radii of the wheel; number of blades 4 to 24, usually 6 to 12.

Forward Curved Blades or Multiblade Fans, the blade being concave in the direction of rotation; number of blades 48 to 64.

Backward Curved Blade Fans, the blades being inclined backward, and convex in the direction of rotation; number of blades, 8 to 12. Operating characteristics of a fan depend largely on the shape of blade. See Fig. 1. All three types have been developed to about the same maximum mechanical efficiency, approximately 80%, determined by the minimum losses of bending the air stream through the wheel, and of air, skin and journal friction. Each type is made single or double inlet, single, double or fractional width, and light, medium or heavy construction, depending on the use of the fan.

For the same work, relative speed varies widely in the three types. To move *standard air, i.e.* air at 68° F. and 29.92 in. Hg, and 50% relative humidity, against 2.5 in. static pressure, the average tip speeds in ft. per min. will be: Radial fan, 5500; forward curved, 4100; backward curved, 7700. At uniform tip speed the pressure produced by the three types also varies widely. Maximum tip speed with standard materials is about 24,000 ft. per min. At this speed and single-stage operation on standard air, expansion and compression being neglected, the pressures produced are: Radial, 48 in. = 1.73 lb. per sq. in.; forward curved, 86 in. = 3.1 lb. per sq. in.; backward curved, 24 in. = 0.87 lb. per sq. in. The number of blades affects speed characteristics more than it does efficiency. The following is the relative rotative and tip speeds of the three types: Radial, lowest rotative, medium tip; forward curved, medium rotative, lowest tip; backward curved, highest rotative, lowest tip. In the forward curved fan the rotative speed is higher than in the radial, despite low tip speed, since for a given duty wheel diameter is lower.

For low volumes at high pressure the radial fan is more practical. For very large volumes at low pressure, either the forward or backward curved fan is preferable. The backward curved fan for ventilation work is best adapted to direct-connected motors, as it can use smaller frame motors than the forward curved type. The radial fan is usually used with steam engine drive.

The Sources of Pressure in a centrifugal fan are the centrifugal force due to rotation of the column of air enclosed between each pair of blades, and the energy in the air due to its velocity when leaving the periphery of the fan wheel. Of two straight-blade fans, of equal diameter and peripheral velocity, that having the longer blades will develop the greater pressure, due to greater centrifugal force.

SIZE OF INLET.—The number of blades has a direct relation to size of inlet. Inlet is made as large as possible, to reduce loss due to friction of air entering the fan. In a wheel of given diameter, more power will be consumed to deliver a given volume of air with a small inlet than with a large one. If d = diam. of inlet, and P_v = pressure due to velocity V, P_v varies as V^2 and inversely as d^4. A small increase in diameter thus greatly reduces inlet loss for a given air delivery. An increase in diameter of inlet decreases the depth of fan blade, thus reducing capacity and pressure. To overcome this, the number of blades is increased to the limit placed by constructional considerations. In a properly proportioned fan, a balance is obtained between the two features

---

* The author acknowledges the assistance of Messrs. M. S. Kice, Jr., of the American Blower Corp., and A. A. Criqui of the Buffalo Forge Co., in the preparation of this chapter.

of maximum inlet and maximum number of blades. With single-width fans, a double intake, where possible, is preferable, as the area of inlet opening is thus doubled and inlet losses are further decreased, resulting in gain of mechanical efficiency. With double-width fans, a double inlet is absolutely necessary.

THE TOTAL PRESSURE in the air delivered by a fan comprises the static pressure or compression, and the velocity pressure due to the kinetic energy of the air. Static pressure is used to overcome resistance of ducts, heaters, etc. Unless used for conveying materials held in suspension in the air, velocity pressure, to be of service, must be converted largely to static pressure, usually by a scroll-shaped casing around the fan wheel and a divergent nozzle on the outlet of the casing, if the velocity of air leaving the outlet is high.

RULES FOR FAN DESIGN.—It is impossible to give any general rules or formulas covering the proportions of parts of fans and blowers. No less than 14 variables are involved in the construction and operation of fans, a slight change in any one producing wide variations in performance. The design of a new fan is largely a matter of trial and error, based on experiments, until a compromise with all the variables is obtained which most nearly conforms to given conditions.

SHAPE OF BLADE.—Fig. 1 shows the effect of curvature of the fan blade. In these velocity diagrams V_2 represents the radial component of the air leaving the wheel, and V_1 its direction relative to the blade. U_2 represents tangential velocity due to rotation of the fan wheel and is equal to the velocity of the periphery of the wheel. R is the resultant velocity, and is the velocity relative to the housing. At a given speed, the forward-curved blade gives a higher pressure than that corresponding to the velocity of blade tip, and is best adapted to wheels in spiral casings. The backward-curved blade gives a lower corresponding pressure and can be used either in a spiral casing or with

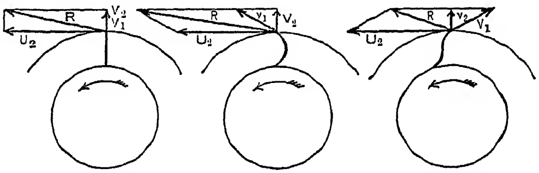

Fig. 1. Types of Fan Blades

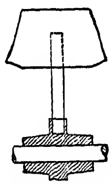

Fig. 2. Radial Fan Blade

a radial diffuser discharging directly to atmosphere. Resolving resultant R into radial and tangential components shows the radial component, as compared to R, to be relatively smaller with forward than with backward curved blades. Without a spiral around the fan wheel the resistance of back pressure is radially inward, hence the blade with the larger radial component is the more efficient.

The standard steel plate fan, in comparison with the multiblade fan, is essentially a straight-blade fan, although the tips of the blades may have a slight curvature, either backward or forward. Straight, radial-blade fans usually have trapezoidal-shaped blades, Fig. 2, to equalize the area of the ports between blades at inlet and outlet. If for constructional reasons, the blade is made rectangular, the area of the ports at inlet and outlet can be kept equal by curving the blades to an involute of a circle; in this case the axial length of blade is $1/4 \times$ diameter of wheel inlet. With blades whose cross-section is the arc of a circle, the minimum width of port between blades is on a line drawn through the tip of one blade normal to the next adjacent blade. The axial length of the blade, therefore, will exceed $1/4 \times$ inlet diameter, depending on the depth of the blade, being greater for shallow than for deep blades. In multiblade fans the inlet diameter closely approaches the diameter of the wheel with a correspondingly greater inlet area. The blades being shallow, their axial length may be from 4 to 8 times the radial depth. The shallowness of the blade is limited by its strength. The principal load on a blade is the centrifugal force due to the weight of the blade. Calculations for strength may be based on the assumption that the blade acts as a beam uniformly loaded.

A later development in blade construction for multiblade fans is described by F. W. Bailey and A. A. Criqui (Some Developments in Centrifugal Fan Design, *Trans*. A. S. H. V. E., 1921). The blade, in cross-section, is a reverse curve, each curve being the arc of a circle. At the heel the blade is concave in the direction of rotation, while at the tip it is convex. This type of blade is claimed to be stronger than the simple curved blade, and better able to resist the stresses due to centrifugal force. It is also claimed

to give pressure characteristics approaching those of the radial-blade fan. (See Pressure Characteristics of Fans, p. 1–58.)

FAN INLETS.—The shape of the inlet to the casing has considerable influence on fan efficiency. If the diameter of the inlet connection is less than the diameter of inlet of the fan wheel, a higher velocity of air is required through the inlet connection than when it is equal to or greater than the inlet of the wheel. Connections for attaching inlet pipes to the casing aggravate this condition. The preferable form of inlet to the casing is a stream-lined conduit which conforms to the natural direction of the flow of air into the inlet. Experiments have indicated a range of mechanical efficiency of from 65 to 70% in a fan with restricted inlet connection, compared to 70 to 80% in the same fan with stream-lined inlet, the volume of air and the static pressure being the same in both cases. The shape of the stream-lined inlet also exercises considerable influence on the mechanical efficiency. Stream-lined inlets are of particular advantage with the wider fans, where the inlet air velocity is high and inlet losses consequently greater.

The effect of obstructions in the inlet, such as bearings and their supports, is marked. The capacity may be decreased as much as 20% and the mechanical efficiency by from 2 to 3%. Due to this fact double-width, double-inlet fans, which require bearings in the inlets, have a lower capacity and efficiency than two single-inlet fans with overhung wheels and unobstructed inlets.

When a fan is used for exhausting, the duct is led to an inlet box fitted to the fan casing. The shape of the inlet box may have a marked effect on the performance of the fan. See *Trans.* A. S. M. E., FSP-54-16, 1932 and FSP-55-9,1933.

M. S. Kice, Jr., says that when double inlet fans are used as exhausters, as for induced draft work, the design of the box must be co-ordinated with the particular fan to which it is applied to enable air to pass through the fan inlet with minimum loss. Properly proportioned rectangular boxes have the advantage of minimum erosion as contrasted with spiral inlet boxes. The fan manufacturer develops these proportions along with the development of the fan.

Some types of multiblade fan inlets (1935) use stationary inlet vanes, curved to direct the air into the fan wheel with a minimum shock loss. Such vanes reduce the capacity, pressure and horsepower of these fans at a given speed, and increase overall efficiency by decreasing shock. Capacity and pressure desired may be obtained by a slight increase in speed, but the increased efficiency results in considerable reduction of horsepower. The vanes increase efficiency proportionately more for the higher capacities, and horsepower is at a maximum and decreases before free delivery condition is reached. This characteristic (see Fig. 5) provides a limit load for a given fan at a specified speed.

The effect of the ratio of diameter of fan wheel to diameter of inlet on the other dimensions and on the efficiency of a steel plate fan is shown by Table 1. In this table the standard fan inlet is 62.5% of the diameter of the wheel. The relative dimensions of fans of other ratios are based upon this standard. A high-efficiency fan, as shown by the table, is tall and narrow, and is therefore more expensive than the ordinary standard commercial fan. This type of fan frequently is used for induced draft work and for direct connection to steam engines.

Table 1.—Relative Dimensions of Steel Plate Fans Operating at the Same Capacity and Pressure

(From Fan Engineering, Buffalo Forge Co., Buffalo, N. Y.)

Diam. Inlet / Diam. Wheel	Diameters, Percent of Diameters of Standard Fan		Width, Percent of Width of Standard Fan	Horsepower, Percent of Horsepower of Standard Fan	Speed, Percent of Speed of Standard Fan
	Wheel	Inlet			
0.700	82.0	91.9	108.9	112.3	123.0
.650	93.2	97.5	102.5	104.0	109.5

.350	255.0	142.8	70.1	77.5	34.6

FAN OUTLETS.—The head of air developed by a fan consists of both static and velocity pressure, the latter ranging from 25% to 50% of the total pressure at outlet. If the fan discharges directly to atmosphere, all velocity pressure at outlet is lost. If the fan is fitted with an evasé discharge piece of proper construction, which will reduce the velocity of the air to from 1000 to 5000 ft. per min., a large percentage of this velocity pressure may be converted into static pressure. This evasé discharge piece should be tapered at an angle of from 7° to 10° from the axis, and should be of sufficient length to

reduce the velocity to the figures above given. Such an evasé discharge piece makes possible a decrease in speed of the fan, and increases the volumetric capacity by from 8% to 12% with an increase in horsepower of but from 3% to 5%, static pressure remaining the same.

PRESSURE CHARACTERISTICS OF FANS.—Pressure characteristics of centrifugal fans are determined by measuring, with a Pitot tube, the total pressure (also known as dynamic or impact pressure) and the static pressure at the fan outlet, at several different percentages of fan outlet opening, ranging from full opening to outlet entirely closed.

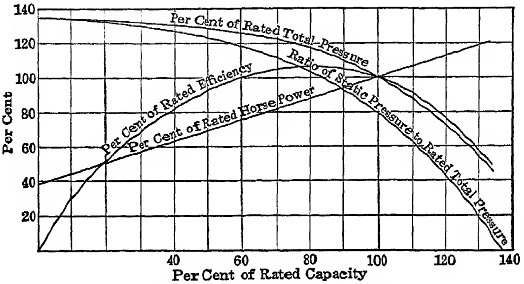

FIG. 3. Characteristic Curves of Radial Blade Fan

The fan is run at a constant speed during the entire test. The horsepower required to drive the fan at each condition of fan-outlet opening is also measured. From the readings, curves similar to those in Figs. 3, 4, and 5 are plotted. In making a fan test, actual quantities, as volume of air, horsepower, pressures in inches of water, etc., are plotted. If, however, these values are converted into percentages of rated performance of the fan under test, the curves may be used to determine the characteristics of any size of fan of similar design.

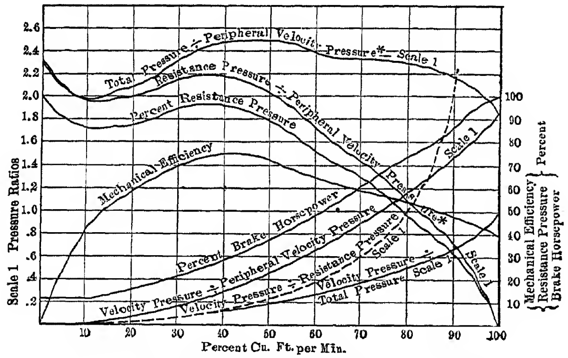

FIG. 4. Characteristic Curves of Forward-curved Blade Fan

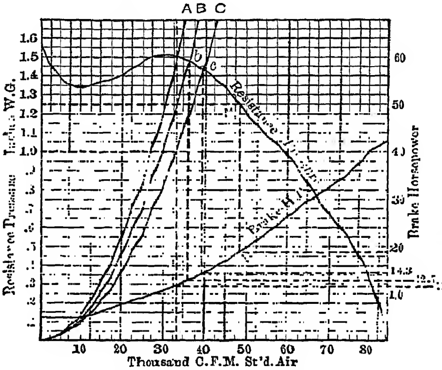
The shape of fan blade greatly influences the form of the characteristic curves. Fig. 3 represents the performance of a straight radial-blade fan. At constant speed, pressure increases as the load on the fan is reduced.

Fig. 4 shows characteristic curves for one type of fan with forward-curved blades. Fig. 5 shows the characteristic curve of a forward-curved blade fan on which are superposed three system curves, which are of value in determining the suitability of a given fan for a given set of conditions. A system curve is plotted on the basis of volume of air required *vs.* the resistance pressure necessary to force it through the system. The inter-

section of the system curve and the fan resistance-pressure curve shows conditions as they will actually occur, and which satisfies both fan and system characteristics. The volume of air delivered is read on the scale of abscissas at the foot of the ordinate drawn through the intersection. The horsepower required is read on the horsepower scale opposite the intersection of the aforesaid ordinate with the brake horsepower curve.

The use of system curves also permits the performance of the fan to be checked against a set of variable conditions, to determine its suitability for a wide variation in volume or resistance pressure.

Example.—A No. 10 Sirocco fan is chosen to deliver 32,950 cu. ft. per min. against a system resistance pressure of 1 1/2 in., requiring 11.71 Hp. at 213 r.p.m. (See Table 6.) If the system resistance pressure is 1 1/4 in. for 32,950 cu. ft. per min. instead of 1 1/2 in. for this same volume, the fan is capable of delivering approximately 50,000 cu. ft. per min. and requires approximately 19 Hp. (See points M and N, Fig. 5), overloading the 15 Hp. motor originally selected to drive the fan. This, however, cannot occur; if 50,000 cu. ft. per min. will flow through the system, the resistance pressure will rise to 2.65 in. Actually, the fan will handle a lesser quantity of air until fan and system characteristics coincide. Curve A shows the system conditions as originally estimated, *i.e.*, with resistance pressure 20% too high. Curve B shows the system conditions as they actually exist. Curve C shows system conditions estimated 20% too low. The intersection of curve B with the fan curve shows at point *b*, that the fan will deliver 36,000 cu. ft. per min. at a resistance pressure of 1.48 in., requiring 12.7 B.Hp. at 213 r.p.m. Curve C similarly shows (point *c*) that the fan under the given conditions will deliver 39,600 cu. ft. per min. at a resistance pressure of 1.44 in., requiring 14.3 B.Hp. at 213 r.p.m. These curves show that had curve *C* been the original estimate, and had the resistance pressure been estimated 50% too low, the fan selected would be capable of delivering the required amount of air without overloading the motor. They further show the importance of considering the system in connection with fan performance.



G. 5. Use of System Curves

Fig. 6 shows characteristics of a double-curved blade, multiblade fan with stationary inlet vanes. (See Fan Inlets.) In this particular fan the blade curves forward from its

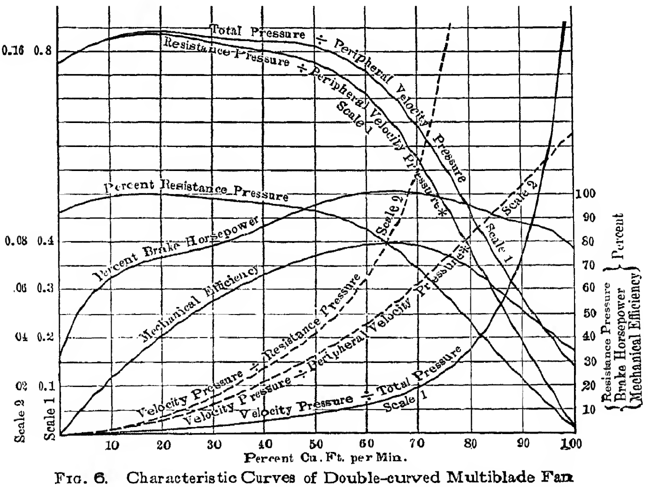


Fig. 6. Characteristic Curves of Double-curved Multiblade Fan

inner edge to about the middle of the blade, at which point the curve reverses, and at the periphery of the wheel the blade has a distinctly backward curvature. The pressure curve rises with a decrease in load in a manner similar to that of a straight radial-blade fan. This type of fan must run at higher speed for a given pressure than a forward-curved blade fan of the same size. The horsepower required is proportionately lower at the higher loads in comparison with the power required at the lower loads. In combination with the rising pressure curve, this indicates that the possibility of overloading the motor is eliminated. For a discussion of the characteristics of the double-curved blade fan, see Some Developments in Centrifugal Fan Design, by F. W. Bailey and A. A. Criqui (*Trans.* A.S.H.V.E., 1921). Fig. 7 shows the characteristics of a backward-curved blade fan.

For every fan running at constant speed there is a pressure and corresponding volume at which a fan will operate at its maximum efficiency (see Characteristic Curves), and a wide variation in these conditions will give a great drop in efficiency. In selecting a fan for any purpose the catalogs and bulletins issued by manufacturers should be examined and a tabular comparison made of the sizes, speed, etc., of different fans which may be used for the given purpose and conditions. (See Fan Tables and Fan Charts, pp. 1–63 to 1–79.)

THE RELATION OF CAPACITY, SPEED, PRESSURE AND HORSEPOWER for a given fan, piping system and density of air are: Let N = speed of fan, r.p.m., or ft. per min. of peripheral velocity; Q = capacity, cu. ft. per min.; V = outlet velocity of

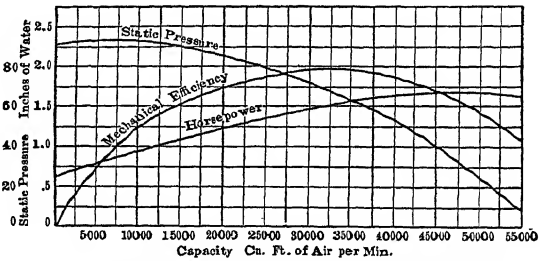

FIG. 7. Characteristic Curves of Backward-curved Blade Fan

air, ft. per min.; h = pressure, in. of water; Hp. = horsepower; D = diam. of fan wheel; W = density of air at absolute temperature t. Then

$$Q \propto N, \sqrt{h}. \quad V \propto N, Q. \quad N \propto \sqrt{h}. \quad h \propto N^2. \quad \text{Hp.} \propto N^3, Q^3, h^{3/2}.$$

For a given symmetrical line of fans, the following relations hold:

	Capacity varies as	Pressure varies as	Horsepower varies as	R.p.m. varies as
At constant r.p.m.	D^2	D^2	D^5	....
At varying r.p.m.	$D^3 \times R$ †	$D^2 \times R$ †	$D^5 \times R$ †	....
At constant tip speed	D^2	Unchanged	D^2	$1/D$
At constant capacity and speed	....	W, $1/t$ *	W, $1/t$ *	....
At constant pressure	$\sqrt{t}$	....	$\sqrt{t}$ *	$\sqrt{t}$

*Approximate. † R = ratio of r.p.m.

RELATION OF VELOCITY AND PRESSURE.—The pressure of the air due to the velocity of the fan blades may be determined by the formula $H = v^2/2g$, or $v = \sqrt{2gH}$, where H = "head" of air, ft., v = velocity of air leaving fan, ft. per second, and g = acceleration due to gravity = 32.2. The pressure of the air is increased by increasing the revolutions per minute of the fan.

The pressure as measured by a Pitot tube is given in inches of water, which may be converted to feet of head H, or to other units as follows:

Let P = pressure, lb. per sq. ft.; P_1 = pressure, lb. per sq. in.; p = pressure, oz. per sq. in.; h = pressure, in. of water; W = weight of air, lb. per cu. ft.; v = velocity of air, ft. per sec.; V = velocity of air, ft. per min. Let the humidity in the air be neglected. Then, since water at 70° F. weighs 62.30 lb. per cu. ft., $P = HW = 5.192\,h$, and $H = 5.192\,(h/W)$.

Substituting the value of H in $v = \sqrt{2\,gH}$, we have $v = \sqrt{64.32 \times 5.192\,(h/W)} = 18.27\sqrt{h/W}$, or $V = 1096.2\sqrt{h/W}$. At 70°F., $W = 0.07494$ (See Table 6, p. 1–05), whence $H = 5.192(h/W) = 69.282\,h$, from which the values of v and V are determined as follows: $v = \sqrt{2gH} = \sqrt{64.32 \times 69.282h} = 66.754\sqrt{h}$ ft. per sec.; $V = 4005\sqrt{h}$ ft. per min.

Since 1 oz. per sq. in. = 1.728 in. of water at 70°F., velocity, when pressure is measured in oz. per sq. in., is $v = 66.754\sqrt{h} = 66.754\sqrt{1.728\,p} = 87.71\sqrt{p}$ ft. per sec.; $V = 5263\sqrt{p}$ ft. per min.

If pressure is measured in lb. per sq. in., at 70°F., 1 lb. per sq. in. = 27.74 in. of water, and $v = 66.761\sqrt{h} = 66.761\sqrt{27.74\,P_1} = 350.89\sqrt{P_1}$ ft. per sec., $V = 21{,}053\sqrt{P_1}$ ft. per min.

The velocity at any other temperature than 70°F., can be found from the formula, $V_2 = V_1\sqrt{t_2/t_1}$, where V_1 and V_2 are velocities and t_1 and t_2 corresponding absolute temperatures, V_1 being the velocity at 70° F. For any other barometric pressure, velocity can be determined from the formula $V_2 = V_1\sqrt{p_1/p_2}$, where p_1 and p_2 are barometric pressures corresponding to velocities V_1 and V_2, respectively.

EFFECT OF HUMIDITY ON FAN PERFORMANCE.—Tables and charts relating to fan performance are based on dry air. The presence of moisture in the air requires, for strict accuracy, a correction according to the formula $V = V_1\sqrt{W/W_1}$, where V and V_1 = respectively, velocity, ft. per min., of air as observed and of dry air; W and W_1 = respectively, cu. ft. per lb. of air as observed, and of dry air. This correction is relatively unimportant for all ordinary cases of fan operation.

EFFECT OF TEMPERATURE ON FAN PERFORMANCE.—In a centrifugal fan, at constant speed and capacity, the horsepower required and the pressure developed will vary directly as the density and inversely as the absolute temperature of the air. If t_1 and t_2 be temperatures in deg. F., the corresponding absolute temperatures will be $(t_1 + 460)$ and $(t_2 + 460)$, and $(t_1 + 460)/(t_2 + 460) = K$. Let p_1 and p_2 be the respective volumes at these temperatures. Then if the volume of air to be delivered at temperatures t_1 and t_2 is constant, $p_2 = p_1/K$ and $\text{Hp.}_2 = \text{Hp.}_1/K$.

.6	3102	1.75	5298	3.75	7756	6.50	10,210	13.0	14,440	....	....

Example.—Required the size, speed and horsepower of fan to handle 30,000 cu. ft. of air per min. at 3/4 in. pressure and at 425° F. *Solution.*—From Table 4, a No. 10 Limit Load Conoidal fan at 350 r.p.m. will deliver 30,312 cu. ft. at 1 1/4 in. static pressure, requiring 8.48 Hp.; it will deliver the same volume at 3/4 in. pressure and 425° F. Horsepower required at 425° F. = $\text{Hp.}_2 = \text{Hp.}_1/K = 8.48/1.67 = 5.08$. For maximum Hp. required at above speed, see limit load figures at bottom of Table 4. At 350 r.p.m., limit load or maximum Hp. will be 9.00, based on 70° air. Correcting for temperatures as above, limit load at 425° F. = 9.00/1.67 = 5.39 Hp.

HORSEPOWER OF FANS.—For a fan of perfect efficiency, the work expended in moving a column of air is the volume of air at 70° F. multiplied by the pressure, or $Q \times P = Q \times 5.193\,h_t$, where Q = volume, cu. ft. per min; P = pressure, lb. per sq. ft.; h_t = total pressure, in. of water. Then $\text{Hp.}_a = QP/33{,}000 = 5.193\,Qh_t/33{,}000$. If Q be taken as 1 cu. ft. and h_t as 1 in., $\text{Hp.}_a = 5.193\,Q/33{,}000 = 0.00015736\,Q$. If $\text{Hp.}_a = 1$ and $h_t = 1$ in., then $Q = 1/0.00015736 = 6355$, whence $\text{Hp.}_a = Qh_t/6355$.

From these equations the brake horsepower of a fan may be determined by the formulas $\text{Hp.}_b = 0.00015736\,Qh_t/E_t = 0.00015736\,Qh_s/E_s$, where h_t and h_s = total and static pressures, respectively, and E_t and E_s = total and static mechanical efficiencies, respectively.

FAN EFFICIENCY.—The *mechanical efficiency* of a fan is $E = \text{Hp.}_a/\text{Hp.}_b$, where Hp._a and Hp._b are air and brake horsepowers respectively. The value of Hp._a is usually

computed by means of the total pressure against which the fan operates, although sometimes the static pressure is used.

Static Efficiency. Total Efficiency. Mechanical efficiency may be stated either as static or as total efficiency. Static efficiency is the ratio of air Hp., calculated by means of static pressure, to brake Hp. That is, $E_s = (Q \times 5.193\ h_s/33{,}000)/\text{B.Hp.}$ Total efficiency is the ratio of air Hp., calculated by means of the total pressure of the air, to brake Hp. That is, $E_t = (Q \times 5.193\ h_t/33{,}000)/\text{B.Hp.}$; Q = cu. ft. of air per min., and h_s and h_t = static and total pressures, respectively, in. of water.

Manometric Efficiency, E_m is variously given by different writers as $E_m = gH/V_b{}^2$ and $E_m = 2\ gH/V_b{}^2$, where H = head of air, ft.; V_b = peripheral speed of fan-blade tips, ft. per sec.; and g = acceleration due to gravity = 32.2. It is defined as the ratio of the pressure developed by the fan to the pressure against a plane surface due to a velocity equal to the peripheral velocity of one fan blade.

Volumetric Efficiency, E_v is the ratio of volume of air delivered per revolution of the fan and the cubical contents of the fan wheel. The term is a misnomer, since it does not fulfill the definition of efficiency, *viz.*: energy recovered ÷ energy expended. The formula for volumetric efficiency is $E_v = Q/\pi r^2 wn$, where Q = volume of air delivered, cu. ft. per min.; r = radius of fan wheel, ft.; w = width of fan wheel, ft.; n = rev. per min.

The terms Manometric and Volumetric efficiency are without much significance and rarely are used in present day fan practice.

SELECTION OF FANS.—The determining features in selecting the proper size of fan for a particular installation are the power requirements and the velocity of air at fan outlet. Some classes of work require absolute quietness of operation, while others do not. The lower outlet velocities are used where quietness is essential. Table 3 represents outlet velocities covering the average range of practice, and can be used in making fan selections. These outlet velocities are lower than those recommended several years ago, since present (1935) types of fans have larger outlets in proportion to other dimensions. Comparative noise tests show fans with fixed inlet vanes to operate at lower noise levels than the same fans without vanes. Experience will assist the engineer in making the best selection for any specific condition. See also notes on Fan Tables and Fan Charts.

Table 3.—Permissible Fan Outlet Velocities

	Supply System	Exhaust System
Churches	800–1000	1000–1400
Schools and Theaters	1000–1400	1200–1600
Hotels and Offices	1200–1600	1400–1800
Factories	1500–2300	1700–2500

FAN TABLES are published in two forms: 1. A rated capacity table giving capacity, speed and horsepower of the fan when operating at point of best efficiency. As a fan frequently operates under conditions other than those of best efficiency, tabular figures should be modified by reference to characteristic curves, when such are available, or by calculation (see below) to ascertain probable performance at other than rated loads. 2. A multi-rating table giving performance of each size of fan at each static pressure at which the fan may operate, showing directly horsepower required by any size of fan to deliver any given volume against any static pressure, and enabling performance of different fans under identical conditions to be compared. Tables 4 to 7 are such tables. Figures for any other size of fan may be calculated from the data in these tables.

Examples in Use of Fan Tables.—In fans operating at constant pressure and with the same outlet velocity: 1. Capacity and horsepower vary as square of diam. D of fan wheel; 2. Speed varies inversely as D.

Example 1.—Required size of a Limit Load Conoidal fan to deliver 13,000 cu. ft. of air per min. at a static pressure of 1 1/2 in. *Solution.*—From Table 3 outlet velocity should be from 1200 to 1600 ft. per min. From Table 4, capacity of a No. 10 fan (60-in. fan wheel) at 1400 ft. per min. outlet velocity is 28,292 cu. ft. per min. From law (1) above $(13{,}000/28{,}292) = (D/60)^2$ and $D = 40.6$. The nearest commercial size of fan (Table 4) has a 42-in. wheel. To obtain exactly 13,000 cu. ft. per min. at 1 1/2 in. static pressure for a 42-in. fan, find from law (1) the corresponding capacity C at 1 1/2 in. static pressure for a No. 10 fan; thus, $(60/42)^2 = (C/13{,}000)$ and C = 26,500 cu. ft. per min. The nearest value of C in Table 4 to 26,500 is 26,271 at an outlet velocity of 1300 ft. per min., which is satisfactory. Opposite this velocity and under 1 1/2 in. static pressure, find the speed to be 361 r.p.m. and Hp. to be 8.6. Applying law (1) to find Hp. for a 42-in. fan, $8.6 \times (42/60)^2 = 4.22$ Hp. From law (2) the speed of the 42-in. fan is $361 \times (60/42) = 516$ r.p.m. The fan selected, therefore, will be a No. 7 (42-in.) Limit Load Conoidal fan operating at 516 r.p.m. and requiring 4.22 Hp.

If it is necessary to select a fan to operate at pressures not covered by the tables, the following laws are applied to convert the given figures to values in the tables. For a given size of fan and

Limit Load for Various R.P.M.

R.p.m.	150	170	190	210	230	250	270	290	310	330	350	370	390	410	430	450	470	490	510	530	550	570	590	610	630	650	670
Hp.	0.708	1.03	1.44	1.95	2.55	3.28	4.14	5.12	6.26	7.55	9.00	10.7	12.5	14.5	16.7	19.2	21.8	24.8	27.9	31.3	35.0	39.0	43.2	47.7	52.6	57.7	63.2

piping system: *a.* Capacity varies directly as speed; *b.* Pressure varies as square of speed; *c.* Speed and capacity vary as square root of pressure; *d.* Horsepower varies as cube of capacity or speed.

Example 2.—Required the size of a Limit Load Conoidal fan to supply 40,000 cu. ft. per min. at $1/8$-in. static pressure, with maximum outlet velocity of 1200 ft. per min. *Solution.*—Find corresponding capacity at $1/4$ in. static pressure by applying law (*c*). $(\sqrt{1/4}/\sqrt{1/8}) = (C/40{,}000)$ whence $C = 56{,}570$ cu. ft. per min. By law (*c*), outlet velocity at $1/4$ in. static pressure is also found to be $1200 \times (\sqrt{1/4}/\sqrt{1/8}) = 1697$ ft. per min. From Table 4, capacity at 1697 ft. per min. may be taken as 34,354 cu. ft. per min. Applying law (1) as before, $(56{,}570/34{,}354) = (D/60)^2$, and $D = 77$ in. The nearest commercial size of fan (Table 5) is 78 in., and from law (1), $(60/78)^2 = (C/56{,}570)$, and $C = 33{,}470$ cu. ft. per min. Interpolating in Table 4, 33,470 cu. ft. per min. at $1/4$ in. static pressure will require 3.91 Hp. at 263 r.p.m., and the outlet velocity will be 1660 ft. per min. Converting these values to a 78-in. fan at $1/4$ in. static pressure, $C = 33{,}470 \times (78/60)^2 = 56{,}570$; r.p.m. $= 263 \times (60/78) = 202$; Hp. $= 3.91 \times (78/60)^2 = 6.61$.

Transforming to $1/8$ in. static pressure to comply with the given conditions,

From law (*c*) $C = 56{,}570 \times (\sqrt{1/8}/\sqrt{1/4}) = 40{,}000$ cu. ft. per min.;
" " (*c*) r.p.m. $= 202 \times (\sqrt{1/8}/\sqrt{1/4}) = 143$;
" " (*d*) Hp. $= 6.61 \times (143/202)^3 = 2.35$;
" " (*c*) Outlet velocity $= 1660 \times (\sqrt{1/8}/\sqrt{1/4}) = 1174$ ft. per min.

The fan selected, therefore, will be a No. 13 (78-in.) Limit Load Conoidal fan, operating at 143 r.p.m. and requiring 2.35 Hp.

Table 5.—Dimensions of Limit Load Conoidal Fans
(Buffalo Forge Co., Buffalo, N. Y., 1934)

Tables 6 and 7 are multi-rating tables of a No. 10 Sirocco fan (forward curved multi-blade), and a No. 10 high-speed fan (backward curved blade), both the product of the American Blower Corp. Both types are built in two classes: Class I fans, for air conditioning or heating and ventilating duty, may be operated for a maximum duty of $3\,3/4$ in. total pressure at 70° F. and sea level without exceeding safe structural limits, and may be used only for the ratings above the heavy black lines in the capacity tables; Class II fans, built primarily for industrial work, may be operated up to total pressures of $6\,3/4$ in. at 70° F. and sea-level. The maximum total pressure for higher temperatures and elevations will be less than those shown in the tables. They *must* be used for all ratings below the heavy black lines in the capacity tables, but may be used for all ratings, if noise is not a factor. The determination for capacity for other sizes than the No. 10 may be accomplished by the same type of calculation as given above. Dimensions of both types are given in Tables 8 and 9.

Table 10 gives capacity of a No. 50 steel plate exhaust fan at various speeds and pressures. Capacities of other sizes can be determined as above described. This fan is essentially a straight radial blade fan, although it is fitted with other types of wheels

(*Continued on* p. 1-71.)

* Inside Dimensions.

for special work. For handling stringy or fibrous material it is fitted with a cast-iron wheel, with smooth curves and surfaces presenting no projections to catch fiber and clog. For long shavings a steel plate straight blade fan is used. The slow speed wheel has steel plate blades with the tips curved forward. For cotton gin work, and for moving dust, smoke or vapors, the so-called cotton wheel is used. This wheel has 18 forward-curved blades. The capacity of the fan fitted with the three latter types of wheel is given in Table 10. See Table 11 for dimensions of all sizes.

Table 12 gives the capacities of blowers for handling air or gases. They are designed to operate at pressures up to 20 in. water gage, and are used for forced draft, cooling molds, blowing scale from dies and forging hammers, ejector exhaust systems for removing inflammable or corrosive fumes, etc. Sizes 3 to 7 are of steel plate construction. Sizes, 0, 00 and 000 are of cast iron. Dimensions are given in Table 13.

built by different makers, Table 14 has been prepared by the National Assoc. of Fan Manufacturers. Fans in the same line are fairly comparable as to size.

FAN CHARTS.—Fan charts perform the same function as multi-rating tables, and enable the proper size of fan for a given service to be easily selected. Two forms are illustrated below.

Fig. 18 is a form of chart used by the B. F. Sturtevant Co. to determine the capacity of steel plate, multivane, and turbovane fans under various conditions of operation, and for the purpose of enabling the proper fan to be selected for a given condition of operation. The lower portion of the chart comprises volume and pressure scales while the upper portion gives curves of total efficiency and of the ratio of total pressure divided by static pressure, together with curves showing the tip speed of the fans at various static pressures. To use the chart, locate point A to correspond with the desired volume in cubic feet per minute and the desired static pressure. A

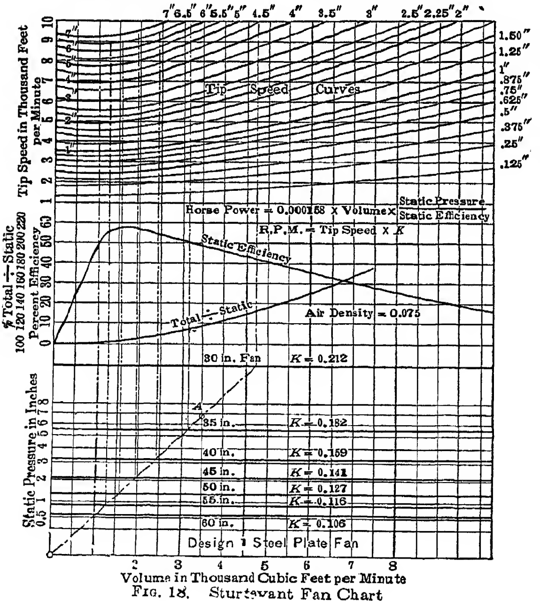

Fig. 18. Sturtevant Fan Chart

Table 14.—Comparison of Commercial Ventilating Fan Sizes. (National Assoc. of Fan Manufacturers, Chicago, 1935)

Figures in the table are the fan size numbers used by the several makers to designate their product. Fan sizes in the same line of each division of the table are fairly comparable.

† Class MV3. [a] Sirocco; [b] Limit-load; [c] Plexiform; [d] Aeroplex; [e] Streamline.

line is drawn through this point and the origin as shown. The ordinate erected at the intersection of this line with the lines corresponding to the different sizes of fan will cut the static efficiency curve, the total divided by static pressure curve and the tip speed curve. The intersection of the ordinate with these curves will give efficiency and tip speed corresponding to volume and pressure assumed. Speed and horsepower are determined then by: R.p.m. = tip speed × K.

Horsepower = (0.000158 × volume × static pressure) ÷ static efficiency. Values of K are given on the lines corresponding to each size of fan.

Example.—Required the size of fan to deliver 3500 cu. ft. per min. against 6 ¾ in. static pressure. The point corresponding to this volume and pressure is shown at A, Fig. 18. Draw a line through A and the origin of co-ordinates, cutting the several fan size lines. Erect ordinates at the points of intersection and continue them to the 6.75 tip-speed curve, intersecting the static efficiency curve and the curve of total divided by static at the middle of the chart. The following data then may be read from the curves:

Fan No.	Volume	Pressure	Efficiency	Tip Speed
35	3500		50.5	Over 10,000
40	3500		54.5	9500
45	3500	6 3/4	56.5	9150
50	3500	6 3/4	57	9000
55	3500		55.5	8900
60	3500	6 3/4	47.5	8900

The tip speed of the 35-in. fan is too high and the 60-, 55-, and 50-in. fans have no apparent advantage in efficiency over the 45-in. fan. The choice, therefore, lies between the 40- and 45-in. fans. Since the difference in efficiency is small, the 40-in. fan is the natural selection. although for induced draft work the selection of the 45-in. fan probably will give better results.

Fig. 19 is a form of chart used by the American Blower Corp. It is a chart for double-inlet, 2/3 double-width fans, based on 690 r.p.m. Similar charts are used for other speeds. This chart will give the size of fan, brake-horsepower, mechanical efficiency and other data required for handling air or gas at temperatures from 70° to 1000° F. The chart is entered on the ordinate of the given static pressure. At the intersection of this ordinate with the line of given temperature on the left side of the chart a horizontal line is drawn to intersect the ordinate of the required volume. The curve of fan sizes nearest the intersection gives the size of fan. At the point where the volume ordinate intersects the brake-horsepower curve of the fan size selected, a horizontal is projected to intersect the given temperature line at the right of the chart. The intersection is on the ordinate of the required brake horsepower.

Example.—Required the size of fan, brake-horsepower and mechanical efficiency to move

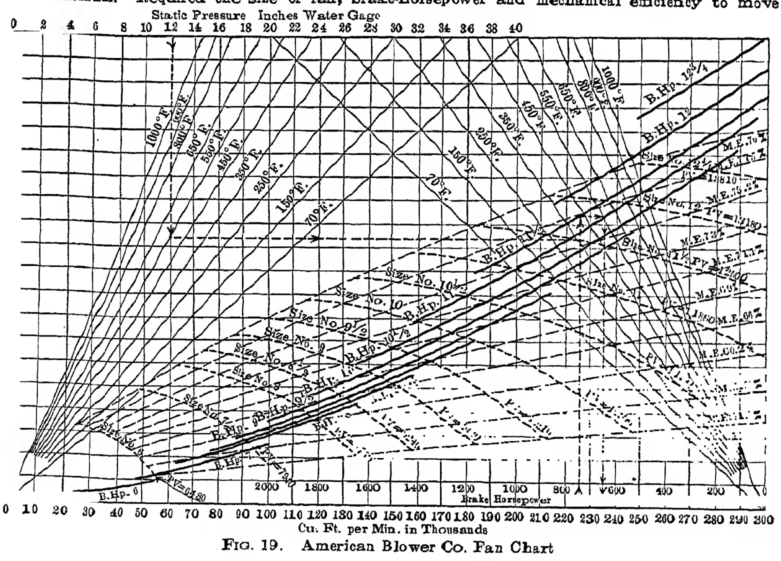

Fig. 19. American Blower Co. Fan Chart

225,000 cu. ft. of air at 550° F. and 12 in. water gage static pressure from entrance of inlet boxes to discharge of fan.

Solution.—Draw a line downward from 12 in. static pressure to intersect the 550° line. Draw the horizontal from the intersection to meet the ordinate 225,000 cu. ft. per min., and read size 11 1/2 fan at their intersection. Extend the ordinate vertically to the 11 1/2 B.Hp. curve, and draw a horizontal from the intersection to the 550° F. line. Follow vertically downward to read 653 B.Hp. The intersection of fan size curve and volume ordinate lies between the 75.2% and 77% mechanical efficiency curves, and may be read as 76% mechanical efficiency. Additional data shown are a cu. ft. per min. of 48.5% of the rated capacity of the fan with standard air (68° F.) and a value of pressure × velocity of 12,500.

2. DISC AND PROPELLER FANS

Mr. H. F. Hagen says that in disc or propeller type fans the air flows in lines substantially parallel to the axis of fan rotation. Such fans are built with a great variety of blade shapes, the different forms modifying the characteristics of performance.

This type of fan has the same change in performance with a change in speed as the centrifugal fan, against the same equivalent orifice. Volume increases directly as the speed, pressure as the square of the speed and horsepower as the cube of the speed; efficiency, ignoring the change in proportion of power consumed by bearing friction, remains constant. These relations have been proved so often by different investigators as to leave no doubt of their accuracy. Theoretically, they also hold for a constant kinematic viscosity. *Kinematic viscosity* is the relation between the viscosity of the air and the speed with which it will propagate a compression, that is, the speed of sound. Within the small range of pressure and temperature differences of air handled by fans, there is an entirely negligible change in kinematic viscosity. The square-cube law, therefore, holds theoretically and experimentally.

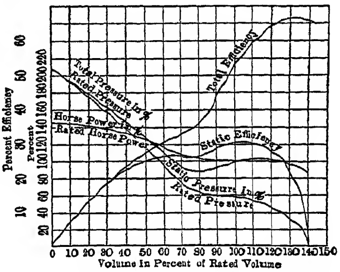

Fig. 20. Characteristics of Axial Flow Fan

The axial flow fan has peculiar characteristics. See Fig. 20. There is always a break in the pressure curves. The horsepower tends to increase from the lowest value at maximum opening and greatest volume to the highest value when the opening is blocked tight, that is, at zero volume. By various designs, the curves can be greatly modified. The reverse curvature in the pressure characteristics can be almost eliminated but the pressure

at this point then becomes unstable. By limiting leakage around the periphery, horsepower can be made nearly constant, but the general features of the curves are always present in greater or less degree.

The pressure curves are really a combination of two different flows of air. When the fan is operating against low resistance and delivering the greater volumes, the air can flow substantially straight through the fan. When the pressure increases to such an amount that at the speed of the portion of the blade near the hub sufficient pressure cannot be developed, all the air can no longer go straight through, but some of it must climb up the blade until it reaches a point where the speed is sufficient to create a pressure equal to that against which the fan is working. The fan then is to some extent working as a centrifugal fan. As the pressure increases, this action becomes more marked. The break in the pressure curves occurs at the point where the action is changing from that of a propeller to that of a centrifugal fan.

DUCTS FOR FANS AND BLOWERS.—The charts, Fig. 22, will enable the selection of the proper size of round or rectangular duct for a given fan installation, or permit the resistance of a given duct system to be determined, from which the proper fan selection can be made. The charts are based on 100 ft. of straight galvanized duct, with proper allowance for the friction of laps and rivets. To determine the size of duct for a given volume of air at a given friction loss, determine the friction loss per 100 ft., and then find on Chart 1 the intersection of the co-ordinate of this friction loss and of the given volume. Read diameter of duct on the duct-diameter line passing through the intersection, and the velocity on the velocity line passing through the same point. If the duct

is rectangular, follow the diameter line into Chart 2. At its intersection with the curve corresponding to one dimension of the duct, draw a horizontal line and read the other dimension on the scale at the right.

EXAMPLE 1.—Find the size of a round duct 175 ft. long, and of a rectangular duct 12 in. wide, that will convey 5000 cu. ft. per min. with a friction loss of $2^3/_4$ in. water gage. *Solution.*—Friction loss per 100 ft. = (100/175) × 2.75 = 1.57 in. Draw a horizontal line through 1.57 on the friction loss scale at left of Chart 1. It intersects the 5000 cu. ft. per min. ordinate just below the 16 in. diam. line, and between the 3500 and 3600 ft. per min. velocity lines. Hence, a 16 in. round duct, with an air velocity of 3550 ft. per min. will fulfill the given conditions. Draw a line

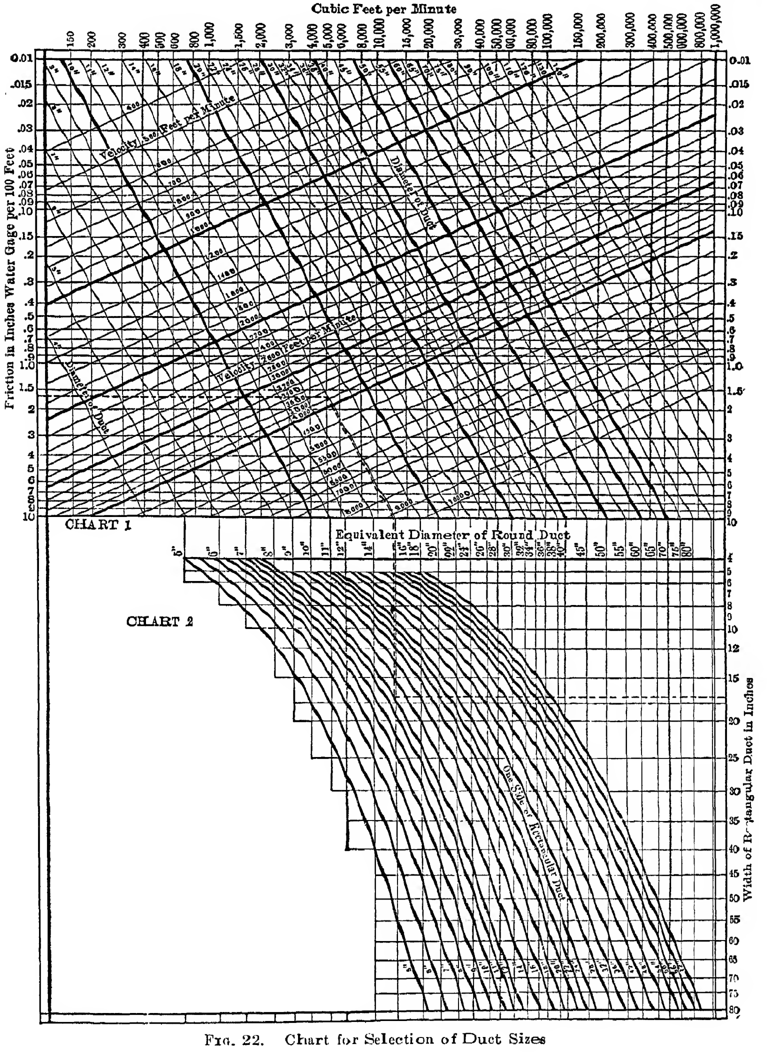

FIG. 22. Chart for Selection of Duct Sizes

parallel to the 16 in. diameter line to intersect the bottom line of Chart 1. Project a line vertically downwards from this point into Chart 2. At its intersection with the 12 in. curve, draw a horizontal line to the scale at the right and read the other dimension of the duct, 17 in.

EXAMPLE 2.—Find the resistance pressure in a rectangular duct system 250 ft. long, handling 15,000 cu. ft. of air per min., the ducts being 18 × 36 in. *Solution.*—The horizontal line through 18 in. width on Chart 2, intersects the 36 in. curve opposite the 28 in. diam. curve on Chart 1. Follow the 28 in. curve to its intersection with the 15,000 cu. ft. ordinate. Follow the horizontal line through this intersection to read a friction loss of 0.8 in. on the scale at the left. Total friction loss = (250/100) × 0.8 = 2.0 in.

Elbows should be considered as an equivalent length of straight pipe, added to the length of the duct. Friction loss should be computed on the total length thus found. Table 18 gives data for such corrections.

Table 18.—Resistance of 90-degree Elbows

D = pipe diameter, R = radius of throat of elbow, L = length of straight pipe of equivalent resistance.

R	L	R	L	R	L	R	L	R	L

3. METHODS OF TESTING FANS

ANEMOMETER METHOD.—Measurements by anemometers are liable to be very inaccurate (see page 1–21) and results obtained by them should be considered only as rough approximations.

WATER GAGE READINGS AT END OF TAPERED CONE.—This method is also far from accurate on account of variable eddies in the air column.

PITOT TUBE READINGS IN CENTER OF DISCHARGE PIPE give fairly accurate results when discharge pipe is the same size as fan outlet, when Pitot tube is placed at a distance of at least 15 diameters of pipe from fan outlet, when the tube is so made that it will give correct readings of static pressure, and when velocities computed from the readings are corrected by a coefficient (0.87 to 0.92 in different experiments) for the ratio between average velocity and velocity at the center of the tube.

PITOT TUBE READINGS IN ZONES OF EQUAL AREA.—The most accurate results are obtained if the tube is traversed across two diameters of the tube at right angles to each other, placing the nozzle successively at points which will divide the cross-sectional area into equal annular areas (with one central circular area). See Test Code, p. 1–83. Since velocity at any point is proportional to the square root of velocity head, it is necessary, for accurate results, to use the square of the average of the square roots of the readings as the mean velocity head of the whole area of the pipe. For low pressures, an inclined manometer should be used with the Pitot tube, containing gasoline instead of water; gasoline keeps the tubes clean, has a definite meniscus and almost no capillary attraction for the glass. Readings of the tube should be corrected for inclination and for specific gravity of gasoline to reduce them to equivalent in. of water.

For accurate scientific work it is well to check the static tube readings by manometer readings from a piezometer ring, which is a narrow annular air-tight channel encircling and soldered to the pipe. Six or more smooth holes bored into the pipe at right angles to its axis connect the interior of the pipe with the ring. The Pitot tube also may be calibrated by means of a Thomas electric gas meter.

THE THOMAS ELECTRIC METER for air and gas consists of an enlargement of section of the flow pipe into a chamber of a diameter equal to about two diameters of the pipe, with conical ends connecting it with the pipe. In the interior is placed an electric heater made of bare resistance wire mounted on a fiber frame and equally distributed over the section of the chamber, and also two electric resistance thermometers, one in front of and the other behind the heater. An electric current, measured by a wattmeter, is passed through the heater and the temperatures before and after the heating are measured by the thermometers. If T_1 and T_2 are the temperatures before and after the heating, H = the heat units corresponding to the watts delivered to the heater (1 watt = 3.145 B.t.u. per hour), and S = specific heat of the air, then the weight of air heated, in pounds per minute, is $W = H \div \{60\,S(T_2 - T_1)\}$.

ACCURACY OF PITOT TUBE MEASUREMENTS.—To obtain even approximately accurate results with Pitot tubes it is necessary both to have the tube properly made and to take great precautions in using it. W. C. Rowse, *Trans.* A.S.M.E. xxxv, p. 633, 1913, tested several forms of tubes, comparing their readings with those of a Thomas

electric gas meter. The best tube was one made of a $1/4$-in. outer and a $1/8$-in. inner thin brass tube, 4 or 5 in. long, soldered together at one end, which was tapered for $3/4$ in. down to the internal diameter of the inner tube, which was thus given a sharp edge. The outer tube was perforated with a smooth hole 0.02 in. diam. at each side at the middle of its length. The rear end of the small tube and each annular space between the two tubes was connected to $1/4$-in. upright tubes, from which rubber tubes led to two manometers. The inner tube received the impact pressure, and the annular space the static pressure. The difference between the two is the velocity pressure, a direct reading of which could be made by connecting the two rubber tubes to the two legs of a single manometer. The manometers were glass U-tubes about $1/2$ in. internal diameter, containing gasoline, inclined 1 vertical to 10 horizontal. The scale was graduated to read 0.01 in. of water column. The results of these tests showed that accuracy within 1% could be obtained when all readings were obtained with a sufficient degree of refinement and when the Pitot tube was preceded by a length of pipe 20 to 38 pipe diameters long. Tests of Pitot tubes with long narrow slots in the outer tube, instead of the small holes, gave results which were in error from 3.5 to 10%.

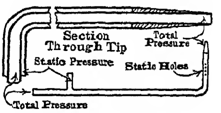

FIG. 23. Pitot Tube

4. TEST CODES FOR FANS

The following test codes for fans and blowers is abstracted from the standard test code of the Natl. Assoc. of Fan Mfrs. and the A.S.H.V.E., second edition, published 1932.

Centrifugal Fans

TEST DUCT is a discharge duct of area equal to fan discharge, straight, of uniform area and section, and not less than 10 diameters long. Readings are taken over a plane at right angles to the duct axis with a Pitot tube parallel to the duct axis, the impact end pointing upstream. Readings are taken at $3/4$ of duct length from fan end. An adjustable device for symmetrically throttling the air is at the outer end of the test duct. See Fig. 24.

STANDARD PRESSURE MEASURING INSTRUMENTS are the double Pitot tube and the manometer. The Pitot tube has not less than 4 static orifices not over 0.02 in. diam. No orifice is located at less than 8 tube diameters from upstream end of tube and at an equal distance from the elbow. The manometers or gages for measuring static pressure and velocity pressure are filled with a light liquid, kerosene, gasoline, or alcohol, and calibrated in position, with rubber tubing attached, by comparison with a calibrated water-filled hook gage whose screw is calibrated to a degree of accuracy commensurate with the accuracy of the proposed reading. The rubber tubing is not removed from the manometer after calibration. The manometer for measuring total pressure is vertical and water-filled.

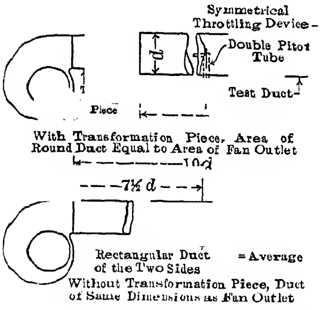

FIG. 24. Arrangement for Centrifugal Fan Test

DYNAMOMETER.—The cradle dynamometer is recommended for all power measurements. Calibrated direct-connected motors may be used. With indirect drive, friction losses are determined for each condition of the test.

NUMBER OF READINGS.—**Round Ducts.**—Not less than 2 traverses of 10 readings each, along diameters at right angles to each other at the centers of 5 equal-area concentric zones across the section of the duct, are made in each test. In small ducts the calibrated nozzle method of Sanford A. Moss may be used for determining volumes. See *Trans.* A.S.M.E. xxxviii, p. 761, 1916. Several nozzles with different size outlets are required to give range of capacity, but if the outlet duct is 20 diameters long with a throttling device midway, the number of nozzles may be reduced.

Rectangular Ducts.—Readings are taken in the center of not less than 16 nor more than 64 equal areas over the cross-section of the duct. With less than 64 readings the centers of the rectangular areas should be not more than 6 in. apart.

ANGLE OF TRANSFORMATION PIECE.—No angle between axis of test duct and any longitudinal element shall exceed 7 deg.

INLET OR OUTLET OBSTRUCTIONS.—Inlets and outlets must be unobstructed except for structural features of fan involved in bearings and their support. A fan provided with bearings is tested on its own shaft and in its own bearings, and run for several hours to wear in. Fans with bearings or bearing supports in the inlets are so mounted for test.

NUMBER OF DETERMINATIONS.—Eight or more determinations from approximately free delivery to no delivery, with approximately equal increments of capacity for discharge area.

OBSERVATIONS AND CALCULATIONS.—Simultaneous readings of total pressure, static pressure, velocity pressure, horsepower input and speed are made. Barometric pressure and wet and dry bulb temperatures in the room and in the discharge duct as close as practicable to point of traverse also are made. Speed is maintained as nearly constant as possible throughout test. Tachometers are always checked by revolution counter readings for periods of not less than 1 min. All air readings are corrected to standard air conditions at fan inlet, *i.e.*, air weighing 0.07488 lb. per cu. ft. These corrections are based on: At constant speed, pressure and horsepower input vary directly as weight of air; velocities corresponding to velocity pressure readings are averaged to obtain average velocity for each traverse, and average velocity pressures are calculated from

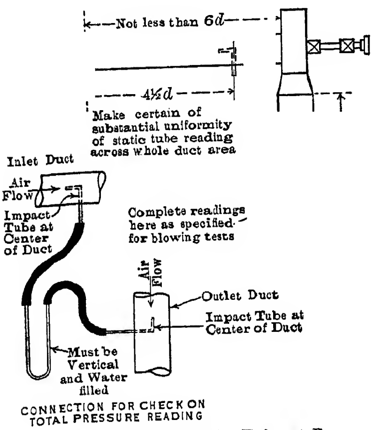

Fig. 25. Arrangement for Exhaust Fan Test

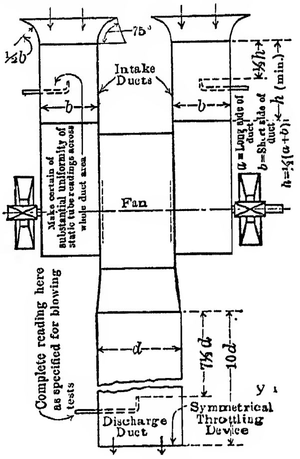

Fig. 26. Arrangement for Exhaust Fan Test with Inlet Boxes

average velocities thus determined. The formula for velocity is $V = 1096.2\sqrt{P_v/w}$, where V = velocity, ft. per min.; P_v = velocity pressure, in. of water; w = weight of air in duct, lb. per cu. ft., as taken from tables of the U. S. Weather Bureau. Capacity for each determination is product of average velocity and duct area, corrected for inlet conditions. Capacity, static pressure, total pressure and horsepower input are corrected to constant speed (see p. 1–58). Total pressure and static pressure also are corrected for duct friction to give conditions at fan discharge, by adding lost head due to duct friction between fan outlet and Pitot tube. This loss will be: For *round ducts*, $f = 0.0257(L/D)P_v$; for *rectangular ducts*, $f = 0.01285\,L\,\{(a + b)/ab\}P_v$, where f = pressure loss, in. of water; P_v = average velocity pressure, in. of water; L = distance from fan outlet to Pitot tube, ft.; D = diam. of discharge duct; a = long side of duct, ft.; b = short side of duct, ft.

RESULTS.—After performance has been calculated for each determination, results, as corrected for standard air conditions and constant speed, are plotted with capacity as abscissas and pressures and horsepowers as ordinates. Smooth curves drawn through these points give pressure and horsepower characteristics, from which data mechanical efficiency is plotted against capacity.

EXHAUSTING FANS.—Capacity is determined by readings in the discharge duct as above prescribed. To determine total pressure an inlet duct is used of area equal to fan inlet and 6 diameters long. See Fig. 25. Total head or total pressure is the difference between average absolute total pressure in discharge duct and average absolute

total pressure in inlet duct, with additions to cover friction of inlet and outlet ducts between points of measurement and the fan, in accordance with the methods previously prescribed. Average absolute total pressure in inlet duct is determined by adding to absolute total pressure in inlet duct the calculated average velocity pressure in inlet duct. Readings in inlet duct are made at 3/4 of inlet duct length from entering end. Static pressure developed by fan is the difference between total head so obtained and the velocity head in the duct.

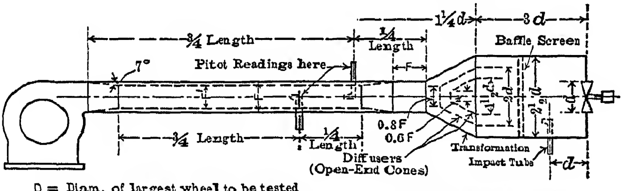
CENTRIFUGAL FANS WITH INLET BOXES are tested with inlet boxes in place. See Fig. 26. Connected to the inlet box is a duct, or ducts for double inlet fans, of the same size and form as the inlet box opening, of length not less than the mean of its two sides, with a nozzle inlet on the open end formed of cylindrical sides as in Fig. 26. Readings are made in test duct at a point 1/2 of a mean side from open end, exclusive of length of nozzle.

TOLERANCES.—A variation of 2 1/2% in determinations of capacity pressure or horsepower will not be considered excessive when applied to the mechanical efficiency.

Disc and Propeller Fans

The code assumes disc and propeller fans to exhaust from a chamber, and all air readings must be taken on the inlet side.

TEST SET-UP for disc and propeller fans consists of an air-tight chamber of rectangular or drum form and of minimum size in proportion to the fan to be tested. See Fig. 27. A duct 10 diameters long, including transformation piece, is on entrance side of chamber. Transformation piece is carried to full dimensions of the end of the chamber and provided with an effective diffuser. Volumes are varied by restriction at inlet end of test duct. Free delivery conditions are procured by an auxiliary blower for obtaining



D = Diam. of largest wheel to be tested
F = Diam. of duct to give velocity of 1800 ft. per min. when testing largest wheel
F' = Diam. of duct coned down to give velocity of 1800 ft. per min. when testing wheels of diameters less than D

Fig. 27. Arrangement for Disc and Propeller Fan Test

zero or above static pressures in the chamber. Capacity of fan is determined by readings in the test duct in the manner prescribed for centrifugal fan tests. In the large chamber, pressure is determined by readings of an impact tube.

DISC FANS TESTED BLOWING are to be tested with the same standard apparatus as shown in Fig. 27 with the addition of a collar on the discharge side of the fan, of the same diameter as fan opening and one diameter long.

MOUNTING.—Any obstruction to flow of air, as a driving motor, pulley, bearing, etc., that forms part of the unit, whether normally on either inlet or discharge side of fan, shall be in its designed position to so affect the test results as to show the true performance of fan as used in that unit.

5. POSITIVE ROTARY BLOWERS

ROTARY DISPLACEMENT BLOWERS ("Roots" type) of the single-stage lobed impeller type are used to move air and gases in all volumes against pressures up to 15 lb. per sq. in., or produce vacuums equivalent to 25 or 26 in. Hg at sea level. The compound type is efficient at pressures up to 25 or 30 lb. per sq. in. They also are used to handle gases and liquids simultaneously in varying proportions, particularly in vacuum processes. The essential parts are two impellers rotated by any suitable prime mover applied to either one or both shafts. Impeller shafts are geared together and impellers revolve in opposite directions. Each impeller traps during one revolution two pockets of the fluid being moved and forces it into the outlet pipe. The impellers can be made with any number of lobes, which are formed by gear tooth curves. A running clearance between the rotating pistons and around the casing prevents internal contact between working parts.

Volumetric efficiency depends on internal clearances, operating pressure and speed

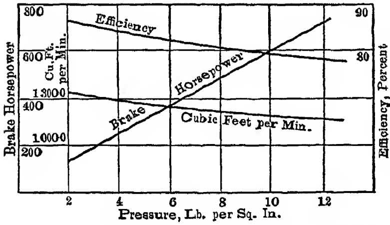
In large, medium-pressure units operating at direct-connected motor speed it may be as high as 98%. When operating at reasonably high speeds there is considerable effect of adiabatic compression; hence, good efficiencies are possible in single-stage operation at pressures up to 12 or 15 lb. per sq. in.; in 2-stage operation up to 25 to 30 lb. per sq. in. Table 19 gives horsepower required for different volumes and pressures. Table 20 gives commercial sizes.

Fig. 28 gives characteristics of a blower operating at constant speed, working against pressures ranging from 2 to 12 lb. per sq. in. Fig. 29 shows characteristics of a blower operated at constant speed and equipped with a power-saving unloading valve to reduce horsepower input to the blower in proportion both to reduction in air pressure and reduction in volume. Fig. 30 gives horsepower and volume curves of a blower driven by a variable speed engine or motor.



28. Characteristics of Blower at Constant Speed and Volume

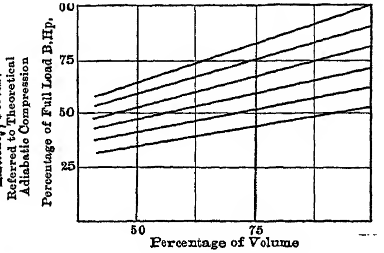


FIG. 29. Characteristics of Blower at Variable Speed

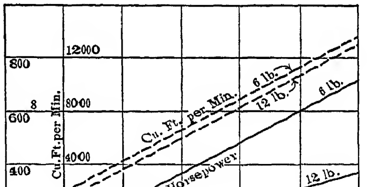
Roots type blowers are used for transmission of manufactured gas, pneumatic conveying systems, agitation and aeration of liquids as in the activated sludge process of sewage disposal, vacuum filtration, foundry cupola and smelting furnace blowing, ventilation of new tunnel workings, scavenging and supercharging Diesel engines, etc. In New York and Chicago they are used on pneumatic tube systems for conveying mail underground from sub-stations to the central post-office. In foundry applications they have been arranged to deliver a constant weight of air, either by manual control or automatically.

Modifications of impeller design permit these machines to be used with high efficiency for pumping heavy, viscous fluids which, due to absence of valve ports, can be handled effectively.



G. 30. Characteristics of Blower Equipped with Unloader, at Constant Speed

SIZE OF BLOWER REQUIRED.—Table 20 gives data on the capacities of blowers, from which the proper size may be selected when the volume of air required is known. An ordinary smith fire requires about 60 cu. ft. of air per min. An ordinary oil furnace burns about 2 gal. of oil per hr., and 1800 cu. ft. of air should be provided per gallon of oil. For quantity of air required by foundry cupolas, see Foundry Practice.

AN EXHAUSTER AND BLOWER is made by Schutte & Koerting Co., Philadelphia, on the principle of the steam-jet ejector. Capacities are given in Table 21. When used

Table 21.—Dimensions and Capacities of Steam-jet Blower and Exhauster

Diameter of Pipes, inches		Capacity per Hour,	Diameter of Pipes, inches		Capacity per Hour,	Diameter of Pipes, inches		Capacity per Hour,
Air	Steam	cu. ft.	Air	Steam	cu. ft.	Air	Steam	cu. ft.
1/2	1/4	300	2	3/4	4,000	5	2	27,000
3/4	3/8	600	2 1/2	1	6,000	6	2	35,000
1	3/8	1000	3	1 1/4	12,000	7	2 1/2	48,000
1 1/2	1/2	2000	4	1 1/2	18,000	8	3	60,000

as exhausters with a steam pressure of 45 lb., these machines will produce a vacuum of 24 in. of mercury, but they can be specially constructed to produce a 28-in. vacuum. When used as compressors, they will operate against a counter pressure equal to 1/7 of the steam pressure. Table 22 shows the time required to evacuate tanks and gives the performance of a 1 1/2-in. exhauster.

Another steam-jet blower is used for boiler firing, ventilation and similar purposes where a low counter pressure or rarefaction meets the requirements. The volumes as given in Table 23 are on the supposition of 60 lb. steam pressure, and a counter pressure of, say, from 0.5 to 2 in. of water.

Table 22.—Performance of 1 1/2-in. Steam-jet Exhauster

TABLE OF CONTENTS

WATER

PROPERTIES OF WATER

EXPANSION OF WATER.—Table 1 gives the relative volumes of water at different temperatures, compared with its volume at 4° C. according to Kopp, as corrected by Porter.

Table 1.—Relative Volume of Water at Different Temperatures

Cent.	Fahr.	Volume	Cent.	Fahr.	Volume	Cent.	Fahr.	Volume
4°	39.1°	1.00000	35°	95°	1.00586	70°	158°	1.02241
5	41	1.00001	40	104	1.00767	75	167	1.02548
10	50	1.00025	45	113	1.00967	80	176	1.02872
15	59	1.00083	50	122	1.01186	85	185	1.03213
20	68	1.00171	55	131	1.01423	90	194	1.03570
25	77	1.00286	60	140	1.01678	95	203	1.03943
30	86	1.00425	65	149	1.01951	100	212	1.04332

Weight of 1 cu. ft. at 39.1° F. = 62.4245 lb.; weight of 1 cu. ft. at 212° F. = 62.4245 ÷ 1.04332 = 59.833 lb.

WEIGHT OF WATER AT DIFFERENT TEMPERATURES.—The weight of water at maximum density, 39.1°, is generally taken at the figure given by Rankine, 62.425 lb. per cubic foot. Some authorities give as low as 62.379. The figure 62.5 commonly given is approximate. The highest authoritative figure is 62.428. At 62° F. the figures range from 62.291 to 62.360. At 32° F. figures given by different writers range from 62.379 to 62.418. Hamilton Smith, Jr. (from Rosetti) gives 62.416. The weights of water per cubic foot from 32° F. to and including 212° F., given in Table 2, are based on the International Critical Tables. The weights over 212° are based on Keenan's Steam Tables. Heat units above 32° F. are from Keenan's Steam Tables.

PRESSURE OF WATER DUE TO ITS WEIGHT.—The pressure of still water in pounds per square inch against the sides of any pipe, channel, or vessel of any shape whatever is due solely to the "head," or height of the level surface of the water above the point at which the pressure is considered, and is equal to 0.43302 lb. per square inch for every foot of head, or 62.355 lb. per square foot for every foot of head (at 62° F.). The pressure per square inch is equal in all directions, downwards, upwards, or sideways, and is independent of the shape or size of the containing vessel. See Table 3.

The pressure against a vertical surface, as a retaining-wall, at any point is in direct ratio to the head above that point, increasing from 0 at the level surface to a maximum at the bottom. The total pressure against a vertical strip of unit breadth increases as the area of a right-angled triangle whose perpendicular represents the height of the strip and whose base represents the pressure on a unit of surface at the bottom; that is, it increases as the square of the depth. The sum of all the horizontal pressures is represented by the area of the triangle, and the resultant of this sum is equal to this sum exerted at a point one-third of the height from the bottom. The horizontal pressure is the same if the surface is inclined instead of vertical.

For an elaboration of these principles see Merriman's Civil Engineers' Handbook or the chapter on Hydrostatics in any work on Physics. For dams, retaining-walls, etc., see Merriman.

The amount of pressure on the interior walls of a pipe has no appreciable effect upon the amount of flow.

BUOYANCY.—When a body is immersed in a liquid, whether it float or sink, it is buoyed up by a force equal to the weight of the bulk of the liquid displaced by the body. The weight of a floating body is equal to the weight of the bulk of the liquid that it displaces. The upward pressure or buoyancy of the liquid may be regarded as exerted at

the center of gravity of the displaced water, which is called the center of pressure or of buoyancy. A vertical line drawn through it is called the axis of buoyancy or of flotation. In a floating body at rest a line joining the center of gravity and the center of buoyancy is vertical, and is called the axis of equilibrium. When an external force causes the axis of equilibrium to lean, if a vertical line be drawn upward from the center of buoyancy to this axis, the point where it cuts the axis is called the *metacenter*. If the metacenter is above the center of gravity the distance between them is called the metacentric height, and the body is then said to be in stable equilibrium, tending to return to its original position when the external force is removed.

Table 2.—Weight of Water and Heat Units per Pound at Different Temperatures

Table 3.—Comparison of Heads of Water in Feet with Pressures in Various Units

One foot of water at 39 1° Fahr. = 62.425 lb. on the square foot;
" " " = 0.4335 lb. on the square inch;
" " " = 0.0295 atmosphere;
" " " = 0.8826 inch of mercury at 32°;
" " " = 773.3 feet of air at 32° and atmospheric pressure;

One lb. per square foot, at 39.1° Fahr.	=	0.01602	foot of water;
One lb. per square inch, at 39.1° Fahr.	=	2.307	feet of water;
One atmosphere of 29.922 in. of mercury	=	33.9	feet of water;
One inch of mercury at 32°	=	1.133	feet of water;
One foot of air at 32°, and 1 atmosphere	=	0.001293	foot of water;
One foot of average sea-water	=	1.026	feet of pure water;
One foot of water at 62° F.	=	62.355	lb. per sq. foot;
One foot of water at 62° F.	=	0.43302	lb. per sq. inch;
One inch of water at 62° F. = 0.5774 ounce.	=	0.036085	lb. per sq. inch;
One lb. of water per square inch at 62° F.	=	2.3094	feet of water;
One ounce of water per square inch at 62° F.	=	1.732	inches of water.

BOILING-POINT.—Water boils at 212° F. (100° C.) at mean atmospheric pressure at the sea-level, 14.696 lb. per square inch. The temperature at which water boils at any given pressure is the same as the temperature of saturated steam at the same pressure. For boiling-point of water at other pressures than 14.696 lb. per square inch, see table of the Properties of Saturated Steam, p. 5–04.

The Boiling-Point of Water May Be Raised.—When water is entirely freed of air, which may be accomplished by freezing or boiling, the cohesion of its atoms is greatly increased, so that its temperature may be raised over 50° above the ordinary boiling-point before ebullition takes place.

It was found by Faraday that when such air-freed water did boil the rupture of the liquid was like an explosion. When water is surrounded by a film of oil, its boiling temperature may be raised considerably above its normal standard. This has been applied as a theoretical explanation of some boiler explosions.

The freezing point also may be lowered, if the water is perfectly quiet, to −10° C., or 18° Fahrenheit below the normal freezing-point. (Hamilton Smith, Jr., Hydraulics, p. 13.)

FREEZING-POINT.—Water freezes at 32° F. at the ordinary atmospheric pressure, and ice melts at the same temperature. In the melting of 1 pound of ice into water at 32° F. about 143.6 heat-units are absorbed, or become latent; and in freezing 1 lb. of water into ice a like quantity of heat is given out to the surrounding medium.

Sea-Water freezes at 27° F. The ice is fresh.

ICE AND SNOW. (From Clark.)—1 cu. ft. of ice at 32° F. weighs 57.50 lb.; 1 lb. of ice at 32° F. has a volume of 0.0174 cu. ft. = 30.067 cu. in.

Relative volume of ice to water at 32° F., 1.0855, the expansion in passing into the solid state being 8.55%. Specific gravity of ice = 0.922, water at 62° F. being 1.

At high pressures the melting-point of ice is lower than 32° F., being at the rate of 0.0133° F. for each additional atmosphere of pressure.

The specific heat of ice is 0.504, that of water being 1. The latent heat of fusion of ice is 143.6 B.t.u. per lb.

1 cu. ft. of fresh snow, according to humidity of atmosphere, weighs from 5 lb. to 12 lb. 1 cu. ft. of snow moistened and compacted by rain weighs from 15 lb. to 50 lb. (Trautwine.)

COMPRESSIBILITY OF WATER.—Water is very slightly compressible. Its compressibility is from 0.000040 to 0.000051 for one atmosphere, decreasing with increase of temperature. For each foot of pressure, distilled water will be diminished in volume 0.0000015 to 0.0000013. Water is so incompressible that even at a depth of a mile a cubic foot of water will weigh only about half a pound more than at the surface.

IMPURITIES OF WATER.—For a discussion of the impurities in water and of water purification, see Boiler Feedwater, under Steam Boilers, p. 6–63.

HYDRAULICS

By William P. Creager

1. FLOW THROUGH ORIFICES AND SHORT TUBES

ORIFICES AND SHORT TUBES.—Fig. 1 shows typical examples of orifices and short tubes. A knowledge of the laws of the flow of water through them is necessary to determine the discharge through sluiceways and the entrances to conduits. If the entrance is not properly shaped, a contraction of the jet occurs as in *a*, *c* and *h*, Fig. 1, and the area of the jet is not as great as that of the orifice or tube. For properly rounded approaches to orifices, as in *b* and *e*, and in the constant-diameter short tubes in *d*, *f* and *g*, the diameter of the jet equals the area of the orifice or tube. In short tubes without rounded entrances, the contraction does occur, but the jet, with certain exceptions as explained below, re-expands as indicated, a partial vacuum occurring just inside the entrance.

Let H = head of water, ft., on the center line of a freely flowing orifice or tube, or the difference in water level for a submerged orifice or tube; a = area, sq. ft., of the orifice or tube; v = theoretical velocity, ft. per sec., corresponding to head H; g = acceleration of gravity = 32.2 ft. per sec.; Q = discharge, cu. ft. per sec.; C_2 = coefficient of contraction, or ratio of area of jet to area of orifice or tube; C_1 = coefficient of friction; C = coefficient of discharge.

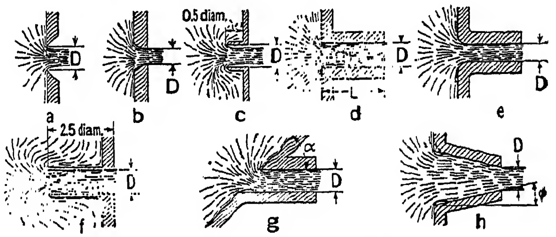

FIG. 1. Types of Orifices

The general equation for the velocity of spouting water is $v = \sqrt{2gH}$ . . . . [1]

Considering friction, the actual velocity due to head H is $v = C_1\sqrt{2gH}$.

The discharge is equal to the product of the actual velocity and the area of the jet, or, since the area of the jet is C_2a, $Q = vC_2a$, or $Q = C_1C_2a\sqrt{2gH}$.

In experiments conducted to determine the discharge through orifices and tubes, the coefficient of friction, C_1, and the coefficient of contraction, C_2, are combined and the general equation for the discharge is $Q = Ca\sqrt{2gH}$ . . . . [2].

The value of C_1 varies with the shape of the orifice or tube. Table 1 gives average experimental values of C, for use in Equation [2] for several types of orifices and tubes.*

These orifices and tubes are circular unless otherwise noted. According to Bovey and other authorities on orifices in thin plates (Fig. 1*a*), the value of C for circular orifices is about 2% less than for square orifices; from 3 to 4% less than for rectangular orifices having a ratio of length to height of 4; and from 5 to 7% less than for rectangular orifices having a ratio of length to height of 10. A similar relation probably exists for tubes having square-cornered entrances. The coefficient C is *not greatly* affected by submergence.

Coefficients for short tubes apply only to heads less than about 40 ft. For higher heads the expansion heretofore explained does not occur and the coefficients C approach those for orifices of similar type.

The expansion of the jet within the short tubes may not occur if they are not submerged and if sufficient friction is lacking, *i.e.*, the jet, after contracting, may pass through the tube without touching its sides, if under a high head; even if the trajectory is such that the jet strikes the bottom of the tube, expansion will not occur if the friction along the bottom is insufficient.

* Where the head is large in comparison with size of orifice or tube. For head or orifice equal to (1.5 × height of orifice), results are about 1% too large.

The shape of the jet from a sharp-cornered round orifice, Fig. 1*a*, between the orifice and the vena contracta, or section at which the area of the jet becomes constant, is indicated in Fig. 2 * and should be used for rounded entrances as in Fig. 1*e*.

Values of C for vertical orifices with full contraction, Fig. 1*a*, with a free discharge into the air, with the inner face of the plate, in which the orifice is pierced, plane, and with sharp inner corners so that the escaping vein only touches these inner edges are given in Table 2, which is an abridgment of tables compiled by Hamilton Smith, Jr., from many experimental data.

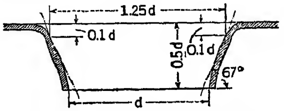

Fig. 2. Standard Mouthpiece

The coefficients in Tables 1 and 2 have been obtained from experiments under ideal conditions. As an indication of the smaller discharge coefficients obtained for practical cases, Fig. 3 gives the results of Stewart's experiments. (Investigation of Flow through Large Submerged Orifices and Tubes, C. B. Stewart, Univ. of Wis. *Bull.* 216, 1908, on the discharge through

4 ft. square submerged sluices of different types). The minimum value of C for each set of experiments is shown. The forms of the entrances to the sluices, Fig. 4, are given as follows: Series A, Square entrance; Series a, Contraction suppressed on bottom; Series b, Contraction suppressed on bottom and one side; Series c, Contraction suppressed on bottom and two sides; Series d, Contraction suppressed on bottom, two sides and top.

The peculiar shape of the curve for Series c is probably an error in the experiments. The experiments covered heads ranging from 0.05 to 0.30 ft. It was found that C was least for heads of 0.15 ft., and these losses are the ones indicated in Fig. 3.

In these experiments, Series A corresponds to Item 1d of Table 1, in which C varied from 0.60 to 0.80, as compared with Stewart's coefficients of 0.60 to 0.784, which is a reasonably close agreement; but Series d corresponds to Item 1e of Table 1 in which C is given as 0.97, as compared with Stewart's variation of 0.925 to 0.882. In the latter case, the considerably lower values of Stewart's coefficient probably were caused in part by an imperfect mouthpiece.

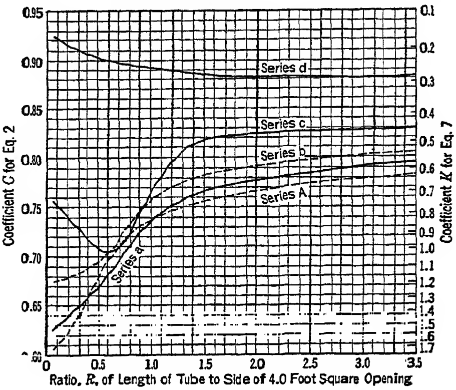

Fig. 3. Values of C and K

VELOCITY OF APPROACH.—If the velocity in the channel of the approach were uniform, the actual head on the orifice or tube would, in reality, be the measured head plus the head corresponding to the velocity of approach. The velocity of approach, however, is not uniform through any section of the channel, being less than the average at the sides and bottom. The velocity directly opposite the orifice therefore is greater than the average, and the effective head on the orifice is the measured head plus a head somewhat greater than that corresponding to the velocity of approach.

Equation [2], corrected for velocity of approach, may be written

$$Q = Ca\sqrt{2g}\,(H + \beta h_v), \quad . \quad . \quad [3]$$

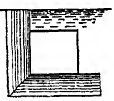

Fig. 4. Stewart's Sluice, Showing Contraction Suppressed on Bottom and Two Sides

where v = average velocity of approach, h_v = head corresponding to this velocity, and β a coefficient which must be determined experimentally. Unfortunately, β is not well known for many types of orifices, and may vary between 1.0 and 2.0, depending upon the location and relative size of the orifice.

RECTANGULAR ORIFICES AND TUBES UNDER LOW HEAD.—If the area of the freely flowing orifice or tube is large in comparison with the head, the equation [1] should be written

$$Q = (2LC/3)\sqrt{2g}\,(H_1^{3/2} - H_2^{3/2}), \quad . \quad . \quad . \quad . \quad [4]$$

where H_1 and H_2 = heads on the bottom and top of the orifice, respectively. If the orifice is completely submerged, the head is the difference in level between the upper and lower water surfaces, and Equation [2] applies.

If, in Equation [4] the top of the orifice is at the water surface, $H_2 = 0$ and the equation reduces to:

$$Q = (2LC/3)\sqrt{2g}\,H^{3/2}. \quad . \quad . \quad . \quad . \quad [5]$$

This is the basic theoretical equation for discharge over weirs. A. H. Gibson says that Equation [2] can be used with an error not greater than 1% if the depth of water to the top of the freely flowing orifice is greater than twice the height of the orifice.

DISCHARGE THROUGH SLUICE GATES.—Sluice gates are made in a variety of forms. Many types of sluices, controlled by sluice gates, are in reality short conduits in which skin friction is a large percentage of the total loss. A discussion of the losses through conduits is given later. See p. 2–10. If the sluice is short, the discharge may be considered as that through a short tube (Figs. 1d to 1h inclusive), or, if the sluice gate is in a thin wall (Figs. 1a to 1c inclusive), the discharge may be obtained from Equa-

tions [2] or [3] with the proper coefficient of discharge selected from Table 1 or Fig. 3 according to the details of the sluice gate opening.

2. FLOW OF WATER IN CONDUITS

HEAD BY BERNOULLI'S THEOREM.—The velocity head, or head required to produce a given velocity, is,

$$\text{Velocity head} = h = v^2/2g \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [5a]$$

According to Bernoulli's Theorem, the general law governing steady flow of water in conduits is as follows: For steady flow in a conduit, the sum of the velocity head, the pressure head, and the potential head at any point, A, is equal to the sum of the corresponding heads at any upstream point, B, less the frictional resistance between the points A and B, Fig. 5.

Expressed mathematically, we have:

$$(v^2/2g) + h_p + h_e = (v_1^2/2g) + h_p' + h_e' - h_f. \quad . \quad . \quad . \quad . \quad . \quad [5b]$$

where v and v_1 = the velocities, ft. per sec., at points A and B respectively; h_p and h_p' = corresponding pressure heads, ft.; h_e and h_e' = the corresponding potential heads above a common datum plane, ft.; h_f = total frictional resistance or lost head, ft., between points A and B.

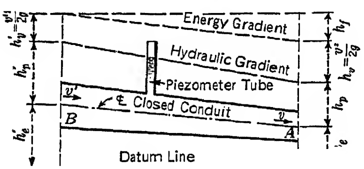

FIG. 5. Closed Conduits

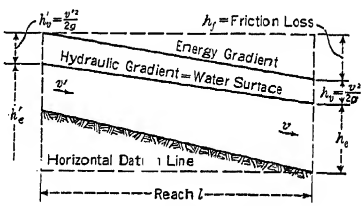

FIG. 6. Open Conduits

If a vertical or oblique tube, Fig. 5, be inserted in a pipe containing water under pressure, the water will rise in the tube, and the vertical height to which it rises will be the head, h_p, producing the pressure at the point where the tube is attached. Such a tube is called a piezometer or pressure measure. If the water in the piezometer falls below its proper level, it shows that the pressure in the main pipe has been reduced by an obstruction between the piezometer and the reservoir. If the water rises above its proper level, it indicates that the pressure there has been increased by an obstruction beyond the piezometer.

If we imagine a pipe full of water to be provided with a number of piezometers, then a line joining the tops of the columns of water in them is the hydraulic gradient, and $h_p + (v^2/2g)$ defines the corresponding elevation of the energy gradient.

In an open conduit, h_e and h_e' are measured to the water surface, as in Fig. 6, and h_p and h_p', measured to the same place, are equal to zero. Therefore, the hydraulic gradient for open conduits is at water surface.

The head lost by friction and eddies between any two points in a closed or open conduit is equal to the drop in level of the energy gradient between the two points. This in turn is equal to the drop in level of the hydraulic gradient, as shown by piezometer readings (or water surface in open conduits), plus the velocity head at the upper point and less the velocity head at the lower point.

CRITICAL VELOCITY.—In capillary tubes, between plates close together, or in large pipes at very low velocity, the friction head varies directly as the velocity. The velocity below which this takes place is the *critical velocity*. Below the critical velocity, the water flows in straight-line filaments, but above it the flow is turbulent and the exponent of v is increased. The critical velocity extends over a considerable range, depending on whether the velocity is increasing or decreasing. For an increasing velocity the critical velocity will be higher than for a decreasing one. King's Hydraulics gives the following values of critical velocities in feet per second, in pipes at a temperature of 68° F:

Diam., in.	1/2	1	2	4	6	12
Lower value	0.53	0.26	0.13	0.07	0.04	0.02
Higher value	3.35	1.68	0.84	0.42	0.28	0.14

FLOW OF WATER IN CLOSED CONDUITS.—The quantity of water discharged through a pipe depends on the *head, i.e.*, the vertical distance between the level surface of still water in the chamber at the entrance end of the pipe and the level of the center of the discharge end of the pipe; also upon the length of the pipe, upon the character of its interior surface as to smoothness, and upon the number and sharpness of the bends. It is independent of the position of the pipe, as horizontal, or inclined upwards or downwards.

The head, instead of being an actual distance between levels, may be caused by pressure, as by a pump, in which case the head is calculated as a vertical distance corresponding to the pressure, 1 lb. per sq. in. = 2.309 ft. head, or 1 ft. head = 0.433 lb. per sq. in.

The total head operating to cause flow is divided into four parts: 1. The *velocity-head*, which is the height through which a body must fall *in vacuo* to acquire the velocity with which the water flows into the pipe $= v^2 \div 2g$, in which v is the velocity in ft. per sec. and $2g = 64.32$; 2. The *entry-head*, that required to overcome the resistance to entrance to the pipe. With sharp-edged entrance the entry-head = about 1/2 the velocity-head; with smooth rounded entrance the entry-head is inappreciable; 3. The *friction-head*, due to the frictional resistance to flow within the pipe; 4. The *eddy losses* due to bends, valves and sudden changes in area of the pipe. All of these heads are lost except the velocity head, a large part of which may be regained at any point by gradual enlargement of the pipe.

Flow of Water in Open Conduits.—The previously explained theory of the flow of water in closed conduits applies directly to the flow of water in open conduits. In the case of open conduits, however, the elevation of the surface of the water is the piezometer or pressure measure.

Loss of Head in Conduits.—The loss of head in conduits may be divided into two general groups: 1. *Eddy losses*, caused by sudden changes in the direction of flow, as at bends, branches, etc., or by sudden changes in velocity due to sudden changes in area, as at the entrance, sudden enlargements, valves, etc.; 2. *Skin friction* in straight, uniform conduits.

EDDY LOSSES IN CONDUITS.—It is convenient to measure eddy losses in terms of the velocity head of the flowing water. The velocity head, or head required to produce a given velocity, may be obtained by transposing Equation [1]:

$$\text{Velocity head} = h_v = v^2/2g \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [6]$$

Then h_f, the head lost at any point in the conduit due to eddies, is

$$\text{Eddy loss} = h_f = Kh_v = K(v^2/2g) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [7]$$

where K = coefficient of eddy loss; v = highest velocity at the point under consideration.

LOSSES AT CONDUIT ENTRANCES.—A direct relation exists between the coefficient of discharge for short tubes and the coefficient of eddy loss K, Equation [7], which can be derived as follows: A drop in pressure or head at the entrance to a conduit is required for two purposes: *a*. Velocity head to provide the necessary velocity; *b*. Head to overcome friction due to eddies. Or,

$$H = h_v + h_f = (v^2/2g) + K(v^2/2g) = (v^2/2g)\ (1 + K).$$

As $Q = av$, $H = (Q^2/2ga^2)\ (1 + K)$. Also from Equation [2],

$$H = (Q^2/2ga^2) \times (1/C^2), \quad \text{and} \quad K = (1/C^2) - 1 \quad . \quad . \quad . \quad . \quad . \quad . \quad [8]$$

The loss of head in short tubes where there is no residual contraction in the jet, as in Figs. 1*d*, 1*e*, 1*f* and 1*g*, and in the sluices used in Stewart's experiments, may be assumed to be the same for similar entrances to closed conduits. Values of K derived from the experimental values of C are given in Table 4.

Table 4.—Coefficients for Eddy Loss for Equation [7]

Fig. No.	Type of Conduit						
1 *d*	Short tube with sharp-cornered entrance, K = ... 0.56						
1 *e*	Short tube with rounded entrance, K = ... 0.06						
1 *f*	Inwardly projecting tube with sharp-cornered entrance,* K = ... 0.56–0.93						
	Inclined tube with sharp-cornered entrance:						
	α = 90°	80°	70°	60°	50°	40°	30°
	K = 0.49	0.56	0.65	0.73	0.78	0.88	0.93

* Depending upon distance of projection.

Values of K for the sluices used in Stewart's experiments, which also are applicable to losses at entrances of similar type, are given in Fig. 3.

LOSSES AT CONDUIT INTAKES.—Losses at the intake racks are usually very small because the velocity must be low to facilitate raking. For clear racks, a safe approximate value of K for use in Equation [7] may be obtained from

$$K = 1.45 - 0.45R - R^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [9]$$

where R = ratio of net to gross area of racks and supports; v in Equation [7] = velocity in the net area of racks and supports. For a usual value of R = 0.65, the resulting value of K is 0.74, and for a usual velocity of 2.5 ft. per sec. in net area, the loss is 0.072 ft. However, allowance should be made for partial closure of the racks with trash. From 25 to 50% of the area of hand-raked racks frequently is obstructed in practical operations if the amount of debris in the water is large. This would increase the above loss to from 0.13 to 0.29 ft. The head losses in well-designed intakes, excepting the loss at racks and gates, are usually negligible, as changes in area are gradual.

Losses at head gates correspond to the losses previously given for conduit entrances. The worst practical condition is that in which the gate is at the head of an entrance similar to Fig. 1*d*. It is possible usually to provide a flare at the upper end of the intake, to produce a gradually increasing velocity between racks and gates, with sides and bottom of the intake nearly flush with the gate opening. In such cases there is a decided eddy only at the top of the gate, and the coefficient K is no greater than about 0.5 in Equation [7], where v is the velocity through the gate. The gradual increase in velocity between the gate and the normal section of the conduit is made without appreciable loss.

Intakes to open flumes vary greatly in type according to the conditions to be met and the ideas of the designer. Losses at the gates must be estimated by comparison with the nearest type of test model indicated in Fig. 3.

EDDY LOSSES AT CONDUIT BENDS.—In the present discussion, values of K used in Equation [7] to derive the losses in bends of conduits, are such as to give a loss in excess of that occurring in a straight pipe of equal length; that is, normal skin friction is not included. The conclusion of a number of experimenters concerning the value of K for 90° bends in closed conduits show an extreme lack of agreement.

Experiments on closed conduits (*Trans.* A.S.C.E., vol. lxii, p. 97; Univ. of Wis. *Bull.* No. 578) tend to show that bends where R_b/d = 5 (approx.) correspond to the minimum

loss in the bend, and hence to the minimum value of K as indicated in Fig. 7. R_b = radius of bend and d = diam. of conduit. Fig. 7 gives recommended values of K for 90° bends in closed conduits, based on available data. The curve representing safe values is an enveloping curve for all experiments. The curve representing probable values is the mean of some of the more recent experiments. Values of K from Fig. 7 should be increased by 50% for screwed pipe elbows, due to the sudden enlargement and contraction of such fittings. It is recommended that values of K for bends other than 90° be taken from Fig. 8.

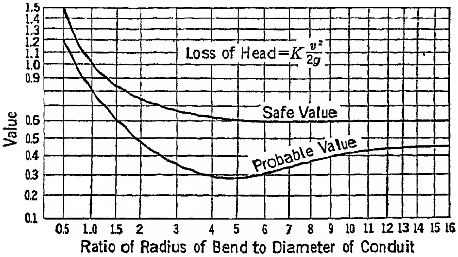

Fig. 7. Values of K for 90-deg. Bends

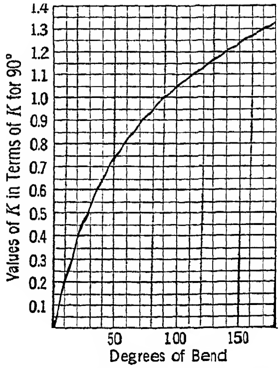

Fig. 8. Values of K for Bends

Few experiments have been made on the losses in bends of open conduits. Fortunately, sharp bends in open conduits usually are not required. Writers often allow for loss at bends of open conduits by adjusting the coefficient C or n (see p. 2–18) of the flow equation. A coefficient is given for a straight open conduit and another coefficient for the same type of conduit "with moderate curvature" or other equally indefinite description. The author believes that no allowance for bends should be made in the flow coefficient C or n, but that the slope for straight alignment should be determined first, and increased slopes provided at bends, corresponding to the best judgment as to additional losses at bends. The few experiments that have been made seem to indicate that the loss due to bends in open conduits is much less than for closed conduits, and values equal to one-half of those in Fig. 7 are recommended. The author has compared such values with experimental data and has found them to agree very closely when one-half the "probable curve" value is used.

For reverse bends in both open and closed conduits, the loss is probably somewhat greater than if the two bends were separated by a considerable length of straight pipe, but the amount of such loss has not been determined.

Recommended safe values for K for miscellaneous fittings are given in Fig. 9.

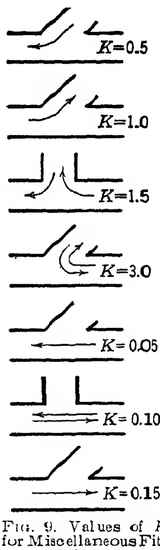

Fig. 9. Values of K for Miscellaneous Fittings

EDDY LOSSES AT CONDUIT VALVES.—The value of K for use in Equation [7] for wide-open gate valves is probably less than 0.1, although few experiments are available. E. A. Dow's experiments on the disc-arm type of butterfly valves indicate a value of

$$K = t/d \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [10]$$

where t = thickness of valve disc; d = valve diameter.

The value of v for use in Equation [7] is that used for the normal section of the conduit.

The author found only three experiments on valves of the Johnson plunger type. On the basis of these experiments he has devised the equation,

$$K = 0.183/\sqrt[3]{d} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [11]$$

where d = diam. at small end, ft. The value of v for use in Equation [7] is that for the small end of the valve.

MISCELLANEOUS CONDUIT EDDY LOSSES.—As all losses, other than those due to skin friction and bends, are due to sudden changes in section of the conduit, knowledge

of the laws governing losses due to sudden contractions and enlargements will assist materially in determining losses caused by various irregularities in conduits. Archer proposes (*Trans.* A.S.C.E., vol. lxxvi, pp. 999-1026, 1913) for the loss due to sudden enlargement in a closed conduit, the equation,

$$h_f = 1.098\ (v_1 - v_2)^{1.919}/2g = 0.01705\ (v_1 - v_2)^{1.919}, \quad . \quad . \quad . \quad . \quad [12]$$

where v_1 and v_2 = velocities in the smaller and larger sections respectively.

An approximate equation giving losses which are correct within 10% for values of $(v_1 - v_2)$, between 1 and 13 ft. per sec. is

$$h_f = (v_1 - v_2)^2/2g. \quad . \quad . \quad . \quad . \quad . \quad . \quad [13]$$

Losses due to gradual enlargements in a closed conduit are not known exactly. Etcheverry gives the value of

$$K = \{1 - (a_1/a_2)\}^2 \sin\theta, \quad . \quad . \quad . \quad . \quad . \quad . \quad [14]$$

where θ = angle formed by intersection of one side of the taper with the center line; a_1 and a_2 = areas of the smaller and larger sections respectively.

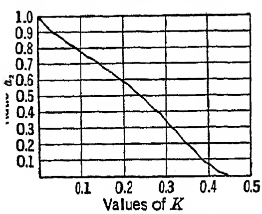

FIG. 10. Values of K for Sudden Contractions in Closed Conduits

Equations [12], [13] and [14] often are used to determine the value of K for sudden enlargements in open conduits and for the junction of a closed and open conduit. This is not correct, as the fundamental principles used in their derivation do not apply to open-water conditions. If the maximum possible loss is to be determined, the value of K should be taken from the equation *

$$K = 1 - (a_1^2/a_2^2). \quad . \quad . \quad . \quad . \quad [15]$$

The value for v for use in Equation [7] is that in the smaller section. This loss is reduced for gradual enlargements in open conduits. Unfortunately, the ratio between the rate of enlargement and the loss is not known exactly, but the loss probably will not exceed 25%, *i.e.*, $K = 0.25$, if the angle of the flare of each side of the conduit makes an angle with the center line not in excess of 2° or 3°.

For sudden contractions in closed conduits, the values of K are given in Fig. 10, which was derived in a manner similar to that employed by Merriman, except that the coefficient of contraction for a sharp-edged orifice, equal to 0.60, was used instead of 0.62 as employed by him in his basic equation. The value of v for use in Equation [7] is that in the smaller section. Losses due to gradual contraction are very small. The loss in gradual contractions in open conduits is negligible.

SKIN FRICTION CONDUIT LOSSES.—Most of the many empirical equations for the uniform flow of water in conduits are based on the equation developed by Chezy in 1775.

$$\text{or in its more general form, } v = CR^nS^m, \quad . \quad . \quad . \quad . \quad [16]$$

where v = average velocity, ft. per sec.; R = hydraulic mean radius, ft., being the cross-sectional area divided by the wetted perimeter; S = sine of the angle of slope of the energy gradient; C, n and m = coefficients depending upon the type of the conduit and the condition of the wetted perimeter, all of which must be determined by experiment.

None of the empirical equations agree very closely with one another and, moreover, they all embody the coefficient C, which must be assumed according to judgment as indicated by available experiments, depending upon the nature and condition of the wetted perimeter. In some equations, n and m are constant for all types of conduits. Other writers have suggested different values for each type of conduit.

A sufficient number of experiments have not been made to enable the engineer to adopt precise coefficients C. The character of the wetted perimeter is liable to considerable change during the life of the conduit, due to corrosion, tuberculation, growth of fungi, weeds, and other vegetation, silt deposits, scour, ice, etc. The chief difficulty in the use of existing experimental data is the lack of the power of definite description of the condition of the wetted perimeter of the experimental conduit. For these reasons, a great refinement in flow equations seems unwarranted at present, and a considerable factor of safety must be adopted to compensate for possible errors in the adopted equation and in the choice of the coefficient C.

At present (1935), Kutter's equation or its approximation, Manning's equation, is mostly used for flow in open channels and the Williams and Hazen equation for flow in closed conduits.

* The exception is where the hydraulic jump is introduced.

Kutter's equation is

$$\frac{\dfrac{1.811}{n} + 41.66 + \dfrac{0.00281}{S}}{0.00281} \sqrt{RS}, \quad . \quad . \quad . \quad [17]$$

where n = coefficient of roughness; R = hydraulic mean radius, ft.; S = sine of angle of slope of the energy gradient.

Manning's equation is

$$v = (1.486R^{2/3}S^{1/2})/n \quad . \quad . \quad . \quad [18]$$

Manning's equation is a simplified approximation of Kutter's equation, and the same values of n that would be adopted for Kutter's equation are to be used.

The Manning and Kutter equations agree fairly closely for conditions which usually obtain in practice, but all published values of n were derived from experiments by use of Kutter's equation.

Williams and Hazen's equation as published in their Hydraulic Tables (John Wiley & Sons, 1920) is

$$v = CR^{0.63}S^{0.54}\,0.001^{-0.04} \quad . \quad . \quad . \quad [19]$$

This may be reduced to $\quad v = 1.32\,CR^{0.63}S^{0.54}. \quad . \quad . \quad . \quad [20]$

Table 5 gives values of R^n and S^m for use in the foregoing flow equations.

As the condition of the surface after a few years, and hence the coefficients n and C, are known only approximately, it is necessary to adopt such values as will result in an error, if any, on the side of safety.

The tabulations given hereinafter have been made from a study of all available sources of information regarding experimental determination of the friction coefficient.* The values corresponding to best and worst conditions embrace practically all variations in the data studied. Isolated values, outside the limits given, have been excluded where there was reasonable doubt as to their accuracy. It is believed that the values given cover the range of practical considerations. The *probable* values are those ordinarily used in practice.

Unless otherwise stated, the friction coefficients in the tables are based on straight or slightly sinuous conduits free from the following influences: *a.* Curvature, other than slightly sinuous; *b.* Settlement of open conduits or other defects of construction; *c.* Sediments, rocks, or other deposits washed or fallen in; *d.* Plant growth, moss, etc.; *e.* Ice covering; *f.* Wind movement.

All experimental data were adjusted as closely as possible to correct for curvature, so that all coefficients are practically for straight conduits. A correction to the calculated slope should be made for appreciable curvature, as indicated heretofore under Eddy Losses at Conduit Bends, p. 2–12. Obviously, the results of defects in construction, settlement, and obstructions are indeterminate, although an attempt has been made in the tabulation to give approximate coefficients for certain conduits which should cover the range of reasonable maintenance.

FRICTION OF ICE COVERING.—It is not known that any experiments have been made to determine the friction coefficient of the under side of a sheet of ice. If the ice had the same effect on friction as the bottom and sides of the conduit, the determination of velocity would be made in the same way as for open-water conditions, except that the width of the ice sheet would be included in the wetted perimeter and the area would be the area under the ice. Although experimental data are not available, it is known that the retarding effect of the under side of an ice sheet is much less than that of the ordinary form of earth and rock canals, and probably equal to that of the smoothest conduits In the absence of a better method, it is recommended that, for ice conditions, the coefficient n for the conduit under open-water conditions be used, and a factor W which is a percentage of the width of the ice sheet, depending upon the roughness of the conduit, as indicated below, be included in the wetted perimeter. In the following tabulation n = value of the coefficient for conduit under open-water conditions, and W = percentage of width of ice sheet to be included in the wetted perimeter.

n =	0.010	0.015	0.020	0.025	0.030	0.035	0.040	0.045	0.050	0.055	0.060
W =	100	87	76	66	58	50	43	37	32	28	25

The probable maximum thickness of the ice sheet depends upon climatic conditions

at the site, the length, width, and depth of the conduit, and the velocity. It can be estimated only by comparison with similar conduits in the vicinity.

Values of Kutter's Friction Coefficient *n* for Straight Open Conduits

DRY EXCAVATED EARTH CANALS.—In general, the value of n in earth canals increases with the life of the canal unless constantly maintained. Slightly silted waters will " slick " over an original rough surface so that the value of n becomes less. Heavily silted water will decrease n, but also will decrease the area of the water prism. Best conditions are found in tough silt or clay soils, with velocities below scouring limits. $n = 0.016$ may be acquired by silt deposit free from growths.

New canals in sandy loam to clay loam range from class above to one next below, and $n = 0.020$.

Medium to Large Canals.—The accepted value for *medium to large canals* in firm earth or gravelly loam with silty water, operated by organization that will give reasonable maintenance, is $n = 0.0225$.

Small ditches, easily influenced by slight roughness, and *larger canals poorly maintained*, $n = 0.025$.

Mountain Power Canals, with cobble bottoms but without finer materials for a graded bedding, $n = 0.028$.

DREDGED EARTH CANALS.—A dredged channel is rougher than one excavated by hand and teams. Likewise, a dipper dredge leaves a rougher bottom than does a drag line. Differences in value of n are largely brought about by adaptability of soil types and silt in the water to smooth over the original roughness. For best conditions $n = 0.0225$; average conditions, $n = 0.030$; worst conditions, without neglect of maintenance, $n = 0.040$.

CANALS EXCAVATED IN ROCK.—It is possible for excavation to be done in horizontally stratified rock, resulting in a very smooth bottom. Such canals, if very wide, will have a very low value of n as the rough sides have relatively little influence and, if the canal is of ordinary size and no attempt is made to smooth the sides, it is considered that the minimum value of $n = 0.020$ approx.

For usual or average conditions, with care in smoothing the rock cut by breaking off projections, $n = 0.033$. Under worst possible conditions, there is no limit, but it is seldom above $n = 0.045$. Silt and gravel deposits in rock canals may lower n by filling in the holes in the bottom.

NATURAL CHANNELS.—It is impossible to describe accurately the conditions of a natural channel that correspond to any given value of n. The best natural channels have a value of n seldom below $n = 0.025$. Average natural channels have a value of n probably in the neighborhood of $n = 0.030$. For the worst possible conditions, there is no limit. Judgment and experience are necessary to fix the value of n accurately for natural channels.

CONCRETE LININGS.—The value of n depends upon the specifications for the concrete surface and the workmanship. Considerable variation in n may result under the same specifications but with different workmen. It should be borne in mind that more favorable values may be attained in construction than should be anticipated in design. The following are the general characteristics:

Best possible, with neat cement, extremely well-troweled surface, $n = 0.010$. This value is seldom realized in practical construction.

The highest grade of practical concrete linings in best condition, with surface troweled as smooth as hand troweled sidewalks, and expansion joints perfectly smooth: Best, $n = 0.011$; probable, $n = 0.012$; worst, $n = 0.013$.

Surface as left by smooth jointed forms, or roughly troweled, and expansion joints fair. The probable value usually is adopted for concrete lining: Best, $n = 0.013$; probable, $n = 0.014$; worst, $n = 0.015$.

Concrete having prominent form marks, or previous types subject to deposits of stones on the bottom: Best, $n = 0.015$; probable, $n = 0.016$; worst, or probable maximum value not subject to rejection because of bad workmanship, $n = 0.018$. If liable to a growth of moss, the foregoing values should be increased by adding 0.002.

Values of n in excess of 0.017 indicate very poor concrete, which may be either badly spalled, owing to frost or to great difference in mixtures of concrete and finish coat, or broken down by the action of alkali. Similar values hold where the channel is losing its identity as a concrete surface, by deposits of sand and gravel or by moss or larval growths. Both moss and larvae appear to thrive in high velocities, even those of 30 or 40 ft. per sec. Covering a channel to exclude sunlight is effective in preventing moss growths and also would tend to prevent larval growth.

GUNNITE LININGS.—Concrete linings deposited by a cement gun, from the inside: Best, if scrubbed with wire brush, $n = 0.016$; average, if not scrubbed, $n = 0.019$; worst, for poor workmanship, $n = 0.021$.

Following a cement gun with a trowel will improve the surface from a capacity standpoint but may induce seepage loss by impairing the original density attained by the process. It is, however, recommended that the surface "rebound" be scrubbed off with a wire broom before it hardens and sticks to the canal bed.

MISCELLANEOUS MASONRY LININGS.—Glazed brickwork: Best, $n = 0.011$; probable, $n = 0.013$; worst, $n = 0.015$.

Brick in cement mortar: Best, $n = 0.012$; probable, $n = 0.015$; worst, $n = 0.017$.

Dressed ashlar surface: Best, $n = 0.013$; probable, $n = 0.015$; worst, $n = 0.017$.

For bench flume, consisting of natural rock surface for the uphill side, a smooth con-

crete retaining wall on the downhill side, and with a floor between, lined with concrete and clean, the uphill side being without projecting points, $n = 0.020$.

For the same construction, but with the floor covered with sand or gravel, or left as excavated without projections, uphill side with a few projecting points, such as obtained with careful excavation in hard rock, $n = 0.025$.

Cement-rubble surface: Best, $n = 0.017$; probable, $n = 0.025$; worst, $n = 0.030$.

Dry-rubble surface: Best, $n = 0.025$; probable, $n = 0.033$; worst, $n = 0.035$.

WOODEN BOX FLUMES.—The following applies to well-constructed flumes, carefully maintained, without projecting calking or other imperfections. Battens where used to be included in wetted perimeter.

Planed lumber, longitudinal boards sides and bottom: Best, $n = 0.011$; probable, $n = 0.014$; worst, after years of service, $n = 0.018$.

Unsurfaced lumber, longitudinal boards sides and bottom: Best, $n = 0.012$; probable, $n = 0.015$; worst, after years of service, $n = 0.018$.

Roofing paper lining varies with the type, generally from $n = 0.010$ to $n = 0.017$.

In general, the best and worst values correspond to new and very old flumes respectively, the latter with patches here and there in place of complete renewal of rotted members and corresponding to rather faulty work.

Wood-stave flumes. Creosoted: Best, $n = 0.011$; probable, $n = 0.012$; worst, $n = 0.014$; Untreated: Best, $n = 0.010$; probable, $n = 0.0115$; worst, $n = 0.014$.

SMOOTH INTERIOR STEEL FLUMES.—For smooth-interior flumes, as manufactured and erected under various trade names. When unpainted: Best, $n = 0.0105$; probable, $n = 0.012$; worst, $n = 0.014$. When painted: Best, $n = 0.012$; probable, $n = 0.013$; worst, $n = 0.017$.

The condition of these patent-joint flumes is largely a function of size and the number of carrying rods. Small flumes (2 to 5 ft. diam.) maintain their catenary shape quite well, if carrying rods are installed midway of each sheet, as well as at the ends, or if the side girders are set close to the sheets. Either method prevents excessive "scalloping." Large flumes require very frequent carrying rods and heavy gage metal.

ROUGH INTERIOR STEEL FLUMES.—Many of the older installations in the U. S. include steel flumes with projecting band joints or steel flumes of corrugated sheet metal. Both of these types are now obsolete and will not be discussed further. A fair value of n for this first type was 0.017, and for the second type 0.022.

Recommended Values of Friction Coefficients for Straight Closed Conduits

CAST-IRON PIPE.—On account of the growth of tubercles on the inside of the pipe, which decreases its area as well as increases its roughness, the value of C for a given age decreases as the diameter, but variation of C with age depends largely upon the composition of the water flowing in the pipe. Values are, therefore, rough approximations. Williams and Hazen recommend the average values given in Table 6. Cleaning old pipe increases the coefficient materially. Experimental values of $C = 150$ have been obtained for best new cast-iron pipe.

STEEL PIPE.—Scobey's equation for flow in steel pipe (U. S. Dept. of Agriculture, *Bul.* 150, 1930) 4 in. size and larger is

$$V = C_1 R^{0.58} S^{0.526} \qquad [21]$$

Values of $R^{0.58}$ and $S^{0.526}$ are given in Table 5.

Scobey divides steel pipe into the following classes, values of C_1 for which are given in Table 7:

Class 1. Full-riveted pipe, having both longitudinal and girth seams held by one or more lines of rivets with projecting heads. (Countersunk rivets belong in Class 3.) 1-*a*. Sheet metal up to 3/16 in. thick; 1-*b*. Plate metal from 3/16 in. to 7/16 in. thick, with either taper or cylinder joints; 1-*c*. Plate metal from 1/2 in. up, with either taper or cylin-

Table 6.—Average Value of C for Cast-iron Pipe

Diam. of Pipe, in.	Age in Years						
	0	5	10	20	30	40	50
4	130	118	107	89	75	64	55
8	130	119	109	93	83	73	65
12	130	120	111	96	86	77	70
16	130	120	112	98	87	80	72
24	130	120	113	100	89	81	74
30	130	120	113	100	90	83	76
36	130	120	113	100	90	83	76
40	130	120	113	100	90	83	77
60	130	120	113	100	90	83	77

der joints, and for plate from 1/4 in. to 7/16 in. thick when butt jointed; 1-*d*. Butt-strap pipe of plate from 1/2 in. up.

Class **2.** Girth-riveted pipe, having no retarding rivet heads in the longitudinal seams, but having the same girth seams as full-riveted pipe.

Class **3.** Continuous-interior pipe, having the interior surface unmarred by plate offsets or by projecting rivet heads in either longitudinal or girth seams. Not necessarily described as "smooth."

Recommended conservative values of C_1, based on experience with eastern waters are given in Table 7. Some engineers claim that western waters are less active. For waters known to be non-aggressive, Scobey recommends that the values of C_1 in Table 7 be multiplied by 1.0026^t, where t = age in years.

SMALL SMOOTH PIPE.—For smooth pipe of brass, lead, tin, glass and drawn copper use Williams and Hazen's coefficients: New and in good condition, $C = 140$; average, $C = 130$; bad, $C = 120$. The same values apply to new small wrought-iron and steel pipe. Falling off of C with age depends upon indeterminate conditions which are accentuated in small pipe. Therefore, an ample factor of safety should be used.

WOOD-STAVE PIPE.—Scobey's equation (U. S. Dept. of Agriculture *Bull.* 376) for flow in wood-stave pipe is

$$v = C_3 R^{0.65} S^{0.555} \qquad [21a]$$

Best information seems to indicate that C_3 does not vary materially with age for wood-stave pipe. Experimental values differ, ranging as follows: Best, $C_3 = 224$; probable average, $C_3 = 185$; worst, $C_3 = 170$.

UNLINED TUNNELS IN ROCK.—No experiments, based on other equations than that of Kutter, have been made. Unless more than usual information as to detail of the surface can be anticipated, use values of $n = 0.035$ to $n = 0.040$, depending on the importance of definite capacity, and compute with the theoretical neat section. In construction, overbreak will run from 10 to 30%, making a larger perimeter and greater area than the theoretical one but giving a correspondingly lower velocity. Two sets of tests disclosed values of n slightly less than 0.035, using a measured discharge but a theoretical neat-section hydraulic radius.

CONCRETE PIPES AND CONCRETE-LINED PRESSURE TUNNELS.—Scobey's equation (U. S. Dept. of Agriculture *Bull.* 852) for flow in concrete lined closed conduits is

$$v = C_2 R^{0.625} S^{0.5} \qquad [22]$$

Without appreciable error this equation may be written

$$v = C_2 R^{0.63} S^{0.5} \qquad [23]$$

Values of $R^{0.63}$ and $S^{0.5}$ are given in Table 5.

Recommended values of C_2 are as follows:

Concrete pipes, adequate for conveyance of city water supply are made in precast units from 8 to 20 ft. long in rigid oiled forms, or centrifugally spun in units 8 ft. long. Steel cylinders, with concrete interior and exterior, yield essentially the same surface. Many experimental data indicate that a value C_2 between 142 and 146 can be expected, but a value of 131 is recommended for design purposes. Large tunnels, concrete lined with oiled steel forms by means of a concrete gun, yield about the same surfaces. Ordinary form work in large bulk will yield results to conform to $C_2 = 121$ or better, depending on the care used in chipping down all offsets and fins remaining from construction. Wood form work now is but little used. Lack of rigidity causes the forms to squeeze under the pressure head of wet concrete. The resulting offsets, crack fins, cavities, etc., conform to a value of $C_2 = 128$ for the best, but may be $C_2 = 89$ for the worst. Concrete is a synthetic product, made by all degrees of workmanship, with all degrees of form excellence. Obviously the best results are obtained by experienced, careful organizations. Usually the difference in cost is more than made up in the relative capacity of the product. Data now available indicate that concrete pipes do not deteriorate in capacity like cast-iron or other metal pipes, by tuberculation. Certain waters may coat concrete and reduce capacity, or algae growths may accomplish this reduction. Reduction from such causes comes quickly or not at all.

Table 7.—Recommended Values of C_1 for Eastern Waters

Class of Pipe	Age in Years					
	0	10	20	30	40	50
3	154	142	131	121	112	104
2	149	138	127	118	109	100
1 *a*	140	130	120	111	103	95
1 *b*	131	120	111	103	95	88
1 *c*	125	115	106	98	90	84
1 *d*	120	110	102	94	87	80

3. MISCELLANEOUS DATA ON CONDUITS

PERMISSIBLE VELOCITIES IN CANALS.—Conditions of economy usually require as small a section and hence as high a velocity as the material will stand. Therefore, if the character of the bed is such as to require low velocities, sedimentation and plant growth are necessary evils, unless the alternative of a smaller lined section is adopted.

A mean velocity of 2 or 3 ft. per sec. generally will be sufficient to prevent the deposit of silt. Sand and gravel entering the canal will not be deposited with velocities somewhat smaller than the maximum given hereinafter to prevent scour of beds of like materials.

Plant growth has seriously affected the capacity of some canals. A temperature below 65° F., turbid or deep water, or a velocity greater than 2.5 ft. per sec. usually prevents serious growth.

The Special Committee on Irrigation Structures of the A.S.C.E. recommends the values given in Table 8 for permissible canal mean velocities to prevent scour. (Permissible Canal Velocities by Fortier and Scobey, *Trans.* A.S.C.E., vol. lxxxix, p. 940, 1926.) This table is for canals on tangents and for depths not exceeding 3 ft. For sinuous alignment reduce velocities 25%. For greater depths use velocities not exceeding 0.5 ft. per sec. greater. Column 3 recognizes that colloidal silts will precipitate and eventually form a plastic, highly cohesive mass, provided the canal is not fully loaded until seasoned. Column 4 recognizes that waters conveying abrasive sand or gravel will furnish a graded bedding and more resistance in some cases, but may assist scour in shales and clays.

AIR-BOUND PIPES.—A pipe is said to be air-bound when, in consequence of air being entrapped at the high points of vertical curves in the line, water will not flow out of the pipe, although the supply is higher than the outlet. The remedy is to provide cocks or valves at the high points, through which the air may be discharged.

WATER-HAMMER.—When selecting valves and fittings, the possibility of shock or strain due to water-hammer, in excess of the average working pressure of the line or system, should be considered. Many valves and fittings, installed where the working pressure under normal conditions would be low, have failed because of pressure due to water-hammer. This danger can be avoided by proper cushioning of the line by air chambers, or by relief valves.

When a valve in a pipe is closed while the water is flowing, the velocity of the water behind the valve is retarded and a dynamic pressure is produced. When the valve is closed quickly this dynamic pressure may be very great. It is then called "water-hammer" or "water-ram," and it causes in many cases fracture of the pipe. It is provided against by arrangements which prevent the rapid closing of the valve.

The excess pressure in feet of water produced by the instantaneous closure of a valve in a pipe is

$$h = av/g \qquad [24]$$

where a = velocity, ft. per sec. of propagation up the pipe; v = reduction of velocity, ft. per sec. The velocity of wave propagation is given by Joukowsky's equation

$$a = 4660/\sqrt{1 + KB} \qquad [25]$$

where K = ratio of the elastic moduli of water to the material of the pipe shell (0.01 for steel pipe); B = ratio of pipe diameter to shell thickness.

Table 8.—Permissible Canal Velocities

Original material excavated for canal	Velocity, ft. per sec., after Aging in Canals Carrying: Clear water, no detritus	Water transporting colloidal silts	Water transporting non-colloidal silts, sands, gravels, or rock fragments
Fine sand (non-colloidal)	1.50	2.50	1.50
Sandy loam "	1.75	2.50	2.00
Silt loam "	2.00	3.00	2.00
Alluvial silts when non-colloidal	2.00	3.50	2.00
Ordinary firm loam	2.50	3.50	2.25
Volcanic ash	2.50	3.50	2.00
Fine gravel	2.50	5.00	3.75
Stiff clay (very colloidal)	3.75	5.00	3.00
Graded, loam to cobbles, when non-colloidal	3.75	5.00	5.00
Alluvial silts when colloidal	3.75	5.00	3.00
Graded, silt to cobbles, when colloidal	4.00	5.50	5.00
Coarse gravel (non-colloidal)	4.00	6.00	6.50
Cobbles and shingles	5.00	5.50	6.50
Shales and hard-pan	6.00	6.00	5.00

Equation [24] applies to any time in seconds of valve closure less than

$$t = 2L/a \quad [26]$$

where L = length of pipe, ft.

The pressure produced by a closure in time greater than $2L/a$ is less than given by Equation [24], but its determination is quite complex. (See Hydro-Electric Handbook, by Creager and Justin, John Wiley & Sons, 1927.)

4. FLOW OVER DAMS

The basic theoretical expression for flow over weirs is given in Equation [5], which, if all constants are combined, may be written

$$Q = Clh^{3/2} \quad [27]$$

where Q = total discharge, cu. ft. per sec.; C = coefficient of discharge, which depends on the shape of the crest and the head on the crest; l = net or effective length of crest, ft., *i.e.*, the total length of crest corrected for end contractions due to piers and sharp-cornered abutments; h = actual or measured head on the crest, ft., taken at a point sufficiently remote from the dam to avoid the surface curve.

Francis has determined, that, to allow for the effect of the velocity of approach, this equation should be written

$$Q = Cl(h + h_v)^{3/2} - h_v^{3/2} \quad [28]$$

where h_v = head corresponding to velocity of approach. An approximate form of Francis's equation is

$$Q = Cl(h + h_v)^{3/2} \quad [29]$$

Equation [29] gives values of Q in excess of that from Equation [28]. The error for a depth of channel approach greater than twice the head on the crest is less than 1%.

Francis's equation for the necessary correction due to complete sharp-cornered end contractions is

$$l = l_t - 0.1nh \quad [30]$$

where l_t = total or gross length of crest between abutments and piers; n = number of complete contractions.

If the crest is obstructed by wide rectangular piers, n represents the number of corners that deflect the water, there being two for each pier and one for each abutment. However, if the piers are very thin or pointed upstream, or if the abutments are well rounded or continuous upstream, the effective reduction in crest will be much less.

For weirs of short length, the contraction can never be greater than about $(1.0 - \sqrt{0.62})/2 = 0.106$ times the clear distance between two piers or abutments, as this corresponds to the side contraction through sharp-cornered orifices having a contraction coefficient of 0.62. Therefore, the contraction at each corner is (0.106 × distance between piers) for all cases where the depth is greater than (1.06 × distance between piers or abutments).

The value of the discharge coefficient C for use in Equations [28] and [29] has been determined experimentally for spillways of many different types. These experiments have been carefully tabulated in Weir Experiments, Coefficients and Formulas, by R. E. Horton (U. S. Geol. Survey, Water Supply Paper 200, 1907). Coefficients adaptable to rounded dam crests, scientifically designed to fit the bottom contraction is given in Hydro-Electric Handbook by Creager and Justin (John Wiley & Sons, 1927). For sharp-crested weirs, as in Fig. 11, the coefficient C is approximately 3.33.

SUBMERGED SPILLWAYS.—If the crest of the spillway is submerged, the discharge coefficients for use in Equations [28] and [29] should be modified according to the degree of submergence, as indicated in Table 9. In this table C is the coefficient for *free* discharge over a similar crest under the same head, and C' is the modified coefficient due to submergence. The head h is the aforementioned head on the dam, and h_s is the corresponding superelevation of tail water above the crest.

Table 9.—Relative Coefficients, Submerged Crest and Free Crest

h_s/h =	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
C'/C =	1.000	0.991	0.983	0.972	0.956	0.937	0.907	0.856	0.778	0.621	0.000

5. MEASUREMENT OF FLOWING WATER *

MEASURING WEIRS.—The measuring weir consists of a dam which may extend the full width of the channel or which may have a crest consisting of a notch, rectangular or otherwise, cut in the dam, in which case it is called a weir with end contractions.

* See also A.S.M.E. Test Code for Hydraulic Power Plants and Their Equipment.

RECTANGULAR WEIRS.—Fig. 11 shows a rectangular weir. The general formula for discharge of water over a rectangular weir is

$$Q = Clh^{3/2} \qquad [31]$$

where Q = discharge, cu. ft. per sec.; l = effective length of crest, ft.; h = head on weir, ft., measured by hook gage or stilling boxes at a distance from the crest between $5h$ and $10h$; C = a coefficient depending upon the type of crest, the head on the weir and the depth of the channel of approach.

Where l_t = total length of crest, ft., the usual expression for the effective length of crest, with two complete sharp-edged end contractions is from Equation [30]

$$l = l_t - 0.2h \qquad [32]$$

Experiments on many different types of crests have been made, which indicate that C varies from about 2.6 for flat-crested dams to about 4.0 for rounded crests scientifically designed to fit the bottom contraction. (See Hydro-Electric Handbook by Creager and Justin, John Wiley & Sons, 1927.) These experiments, with the resulting values of C, are summarized in Weir Experiments, Coefficients and Formulas by R. E. Horton (U. S. Geol. Survey, Water Supply Paper 200, 1907). Measurement of discharge over existing dams of similar types of crest can be made by comparison with these experiments within only a fair degree of accuracy.

Unless duplicating exactly a given set of accurate experiments, measuring weirs, constructed for that purpose, should have the following characteristics: 1. Straight uniform channel with uniform velocity, provided by stilling racks if required; 2. Suppressed end contractions, provided by making sides of channel form the end of the weir. This results in $l = l_t$ in Equation [32]. 3. Weir to have free overfall with complete aeration of the nappe. Aeration usually requires air passages leading to the space between the nappe and the dam; 4. A metal crest free from rust, with sharp right-angle corner on the upstream edge, a crest width of 1/8 in. and beveled to an angle of 45° on the downstream face.

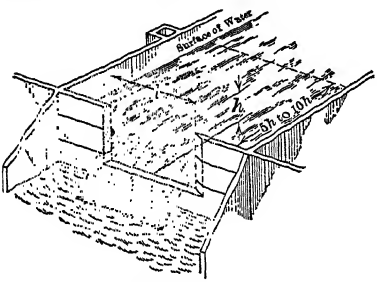

Fig. 11. Weir and End Contractions

A number of equations, based on experiments with sharp-crested rectangular weirs of the foregoing specifications, have been proposed. The following apply to such weirs with suppressed end contractions:

Francis Weir Equation.—The best known equation is that of Francis (Lowell Hydraulic Experiments, by J. B. Francis), which is

$$Q = 3.31l\left[(h + h_v)^{3/2} - h_v^{3/2}\right] \qquad [33]$$

where h_v is the head due to the velocity of approach. With no velocity of approach, Equation [33] reduces to $Q = 3.31lh^{3/2}$. [34]

Francis's equations are subject to considerable error, particularly for high velocities of approach and small values of h. The equation should not be used for accurate weir measurements and is given here only because Equation [34] is a convenient one to remember for rough approximations.

Fteley and Stearns Weir Equation.—(Description of Some Experiments on the Flow of Water, by Fteley and Stearns, *Trans.* A.S.C.E., xii, p. 1, 1883.) This equation is:

$$Q = 3.31\,l\,(h + 1.5h_v)^{3/2} + 0.007l. \qquad [35]$$

Equation [35] is the result of a study of their own experiments and those of Francis. The range of conditions covered by these experiments is given in Table 10. Fteley and Stearns's experiments indicate discharges under low heads about 3% less than those of Bazin.

Table 10.—Range of Conditions in Fteley and Stearns' Experiments

	Francis	Fteley and Stearns	
		With End Contractions	Without End Contractions
Limit of head	0.6 to 1.6 ft.	1.0 ft.	0.83 and 1.63 ft.
Height of weir	2.0 and 5.0 ft.	3.56 ft.	3.17 and 6.55 ft.
Length of weir	8.0 and 10.0 ft.	2.30 to 4.00 ft.	5.00 and 19.00 ft.
Width of channel approach	10.0 and 14.0 ft.	....	....
Maximum velocity of approach	0.2 to 1.0 ft. per sec.	0.54 ft. per sec.	0.6 and 0.8 ft. per sec

Bazin Weir Equation.—(Translation by Marichal and Trautwine, *Proc.*, Engrs. Club of Philadelphia, 1890.) Bazin derived his equation from his own experiments. It is written for weirs without end contractions as

$$Q = \left(0.405 + \frac{0.00984}{h}\right)\left(1 + 0.55\frac{h^2}{D^2}\right) lh\sqrt{2gh}. \quad . \quad . \quad . \quad . \quad . \quad [36]$$

where D is the depth, ft., of water upstream from the weir.

The experiments covered the following range of conditions: Range of head 0.3 to 1.78 ft.; height of weir 1.16 to 3.72 ft.; length of weir 1.64 to 6.56 ft.

King Weir Equation.—King (Handbook of Hydraulics, by H. W. King, McGraw-Hill Book Co., 1929) proposes the following equation, which, after considerable study, he finds to agree more closely with various experimental data than any of the others:

$$Q = 3.34lh^{1.47}\{1 + (0.56h^2/D^2)\}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [37]$$

Rehbock's Weir Equation.—Perhaps the most accurate of all weir equation is that of Rehbock. (See discussion of Precise Weir Measurements, by Schoder and Turner, *Trans.* A.S.C.E., vol. xciii, 1929.) If P = height of weir, ft., this equation is

. . . . . . [38]

CHOICE OF TYPE AND METHOD.—As no equations have been derived which will agree exactly with experimental data, precise measurements should be made under conditions identical with those under which some one set of original experiments were made. Bazin's experiments are by far the most complete, but they have not been proved to be more accurate than those of Fteley and Stearns. As the latter indicate discharges for low heads somewhat less than those of Bazin, they have been used extensively for measurements where an error, if any, would result in a determined flow less than the actual.

On account of the disagreement between the various proposed equations, the preliminary draft of the A.S.M.E. Test Code for Hydraulic Power Plants and Their Equipment specifies the use of Equation [31] for sharp-crested rectangular weirs without end contractions. Coefficient C is taken from Table 11, which gives values including the correction for the velocity of approach.

The coefficients in Table 11 are the average of values computed by the equations of Fteley and Stearns, of Bazin, and of Rehbock.

TRIANGULAR NOTCH WEIRS.—Triangular or V-notch weirs, in which the apex is down, are adaptable to small discharges. In this type of weir, the head for extremely small discharges is proportionally greater due to the reduction of crest length near the apex. This results in greater accuracy.

From his own experiments and those of Barr, King (Handbook of Hydraulics, Second edition, p. 93) gives the following equations for discharge: For a sharp-edged right-angle notch cut in a large sheet of commercial steel plate, $Q = 2.52\,h^{2.47}$; . . . . [39]
For a similar notch cut in a polished brass plate, $Q = 2.48\,h^{2.48}$. . . . . [40]

D. R. Yarnall (*Mech. Engg.*, Jan., 1927) gives the following coefficients for the equation

$$Q = Ch^{5/2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [41]$$

Head, h	0.4	0.6	0.8	1.0	1.2
Coefficient, C	2.511	2.492	2.484	2.481	2.480

These coefficients apply to a right-angle notch cut in a smooth brass plate, with edges very carefully finished but not highly polished. An accuracy within 1/2 of 1 percent is claimed.

THE CIPPOLETI, OR TRAPEZOIDAL WEIR.—Cippoleti found that by using a trapezoidal weir with the sides inclined 1 horizontal to 4 vertical, with end contraction, the discharge is equal to that of a rectangular weir without end contraction (that is with the width of the weir equal to the width of the channel) and is represented by the simple formula $Q = 3.367\,lh^{3/2}$. A. D. Flinn and C. W. D. Dyer (*Trans.* A.S.C.E., 1894), in

Table 11.—Test Code Values of C for Various Heads and Heights of Crest

Head, h	Height of Crest, P										
	4	5	6	7	8	9	10	12	14	16	20

experiments with a trapezoidal weir, with values of l from 3 to 9 ft. and of h from 0.24 to 1.40 ft. found the value of the coefficient to average 3.334, the water being measured by a rectangular weir and the results being computed by Francis's formula, and 3.354 when Smith's formula was used. They conclude that Cippoleti's formula when applied to a properly constructed trapezoidal weir will give the discharge with an error due to combined inaccuracies, not greater than 1%.

CURRENT METERS.—The current meter is a mechanism consisting of an arrangement of cups or vanes, on vertical or horizontal axes, respectively, held stationary in a stream of flowing water. The vanes are revolved by the motion of the water. The number of revolutions in a given time is proportional to the velocity of flow. The number of revolutions is usually made known to the observer by the making and breaking of an electric circuit as indicated by a buzzer or on a recording device, or by sound conveyed through a tube used to hold the meter. Current meters are rated by drawing them through still water at several velocities. The meter should be rated before and after each test.

Current meters are not extremely accurate means of testing, on account of the vertical and horizontal components of flow in streams caused by eddies. Some meters are retarded and others accelerated by turbulent flow. The amount can be gaged by holding the meter obliquely during rating. For greater accuracy, two types of meters should be used which have opposite characteristics due to turbulence, and the weighted average of the readings used.

The section of the stream used for the test should be as uniform in area and as smooth as possible for some distance up and down stream. Observations should be made at a sufficient number of points in the gaging cross-section to accurately determine the average velocity, the spacing of observations being ordinarily closer towards the sides, top and bottom, where the change in velocities is greatest. Vertical and horizontal velocity curves should be plotted from which to calculate the mean velocity.

For a discussion of different types of meters, see Effect of Turbulence on the Registration of Current Meters, by Yarnell and Nagler, *Trans.* A.S.C.E., vol. xcv, 1931, p. 766.

FLOAT MEASUREMENTS.—The velocity of the stream can be found by laying off 100 ft. of the bank and throwing a float into the middle, noting the time taken in passing over the 100 ft. By doing this a number of times and taking the average, the velocity at the surface is determined by dividing the average by the distance. As the top of a stream flows faster than the bottom or sides, the average velocity being about 83% of the surface velocity at the middle, it is convenient to measure a distance of 120 ft. for the float and reckon it as 100.

PITOT TUBES.—The Pitot tube is used for measuring the velocity of flowing fluids and gases. Its essential feature is a thin-edged orifice placed at right angles to the flow at the end of a tube. The impact of the fluid causes an excess pressure in the tube equal to the velocity head. In general, the Pitot tube consists of a tube passing through a stuffing box in the shell of the pipe, the end of which is bent at right angles upstream and tapered to form the orifice. The orifice is made to traverse the pipe and at least two diameters mutually perpendicular should be traversed. The pressure in the tube is

$$H = h_p + h_v = h_p + (C^2 v^2/2g), \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [42]$$

where h_p and h_v = the pressure and velocity heads respectively, and C = a constant.

Since the pressure in the tube is the pressure head plus the velocity head, the Pitot tube reading must be compared with the average of at least four piezometers placed around the pipe to measure the pressure head. The piezometers consist of tubes connected to $^1/_8$- or $^1/_4$-in. openings flush with the inside wall of the pipe. The wall of the pipe near the piezometers should be particularly smooth and should be free from burrs.

According to Allen and Hooper (Piezometer Investigation, *Trans.* A.S.M.E., Hyd. 54–1, 1932) square-edge piezometer openings are very sensitive to slight defects, and they recommend $^1/_8$- to $^1/_4$-in. holes with inner edges rounded to $^1/_{32}$ to $^1/_{16}$ in. radius respectively. The tube connected to the piezometer will read exactly the pressure head h_p.

The Pitot and piezometer tubes usually are joined through a manometer in which the differential head is directly measured. The differential head is, from Equation [41],

$$h_v = H - h_p = C^2v^2/2g, \text{ from which } v = C\sqrt{2gh}\,, \quad . \quad . \quad . \quad . \quad [43]$$

where C = about 0.98, but should be determined experimentally.

Pitot tubes are not extremely accurate unless the flow in the pipe is extremely smooth and straight, because whorls and eddies greatly affect the readings.

Many forms of tubes are used. In the pitometer, the Pitot tube and the piezometer tube encased in a larger tube, pass through the stuffing box and traverse the pipe diameter simultaneously.

THE VENTURI METER.—The Venturi meter, as shown in Fig. 12 consists of a contraction in a pipe or other closed conduit for the purpose of accelerating the fluid and lowering its static pressure. Piezometers are placed at A, the upstream end of the contraction and at B, the lower end. The equation for the discharge past the meter is

. . . . [44]

where Q = discharge, cu. ft. per sec.; A = area at A, sq. ft.; a = area at B, sq. ft.; h = difference between the pressure heads at B and A, as shown by the piezometers; C = a coefficient which varies between 0.97 and 1.0.

From data in Part 1 of the A.S.M.E. Fluid Meters Report, 1924, the author has devised the following empirical formula for the value of C for water:

$$0.051 \qquad [45]$$

where S = velocity at the throat, ft. per sec.; t = temperature of the water deg. F.; d = diameter at the throat, in.

FIG. 12. Venturi Meter

King (Handbook of Hydraulics, 2nd edition, p. 381) claims that more recent experiments by Ledoux (Venturi Tube Characteristics, *Trans.* A.S.C.E., lxi, 1927) indicate values of the coefficients to be about 2% smaller for throat velocities of 5 ft. per sec., and about 1% smaller for the higher velocities. However, the exact determination of the coefficient can be obtained only by test.

Equation [45] applies for meters having the following usual dimensions, where D is the normal diameter of the pipe: Diameter of the throat at B from $D/4$ to $D/2$; length of the throat at B from $D/4$ to $D/2$; entrance cone to have a total angle of about 21°; exit cone to have a total angle of about 5° to 7°; throat to be accurately machined to exact diameter; diameter at A to be smooth and to accurate dimension; angles in entrance cone at B to be rounded off to an easy tangential curve; length of straight pipe before meter at least $5D$, and preferably more.

The tubes from the piezometers A and B are joined through a manometer and the differential pressure h_v read directly. Special attachments may be obtained for indicating, recording and integrating the flow.

The loss of head in passing through the meter can be calculated from Equation [14], practically the entire loss being confined to the enlargement below the throat.

There is no limit to the sizes of the meters nor the quantities of water that may be measured. Three Venturi tubes, approximately 17 ft. diameter, are installed in the Catskill Aqueduct supply to New York. While the Venturi meter originally was applied to the measurement of water it has since been used extensively for the measurement of sewage, gases, steam and many other fluids.

Any sudden reduction in pipe diameter may be used as a Venturi meter if properly calibrated by other means of measuring the flow. Examples of such uses are at the reduction of penstock diameter at entrance to hydraulic turbines and in the scroll cases of such turbines for permanent meters for recording changes in discharge. See Mechanical Features Affecting Hydro Plants by E. A. Dow, *Mech. Engg.*, Oct. 1925.

Many other modifications of the Venturi meter are in use, including contractions in open conduits. (See The Improved Venturi Flume, by R. L. Parshall, *Trans.* A.S.C.E., 1926, p. 840.)

Thin plate or sharp-edged orifices in pipes used for measuring flow are merely a rounded hole in a flat diaphragm clamped between the pipe flanges at a joint in the pipe line, with the hole concentric with the pipe. The theory of measurement is the same as that of the Venturi meter.

MEASUREMENT OF DISCHARGE OF PUMPING-ENGINES BY MEANS OF NOZZLES.—(*Trans.* A.S.M.E., xii, 575)—The measurement of water by computation from its discharge through orifices, or through the nozzles of fire-hose, furnishes a means of determining the quantity of water delivered by a pumping-engine which can be applied without much difficulty. John R. Freeman (*Trans.* A.S.C.E., Nov., 1889), describes a series of experiments covering a wide range of pressures and sizes, and the results showed that the coefficient of discharge for a smooth nozzle of ordinary good form was within one-half of 1%, either way, of 0.977; the diameter of the nozzle being accurately calipered, and the pressures being determined by means of an accurate gage attached to a suitable piezometer at the base of the play pipe.

In order to use this method for determining the quantity of water discharged by a pumping-engine, it would be necessary to provide a pressure-box, to which the water would be conducted, and attach to the box as many nozzles as would be required to carry

off the water. According to Mr. Freeman's estimate, four 1¼-in. nozzles, thus connected, with a pressure of 80 lb. per sq. in., would discharge the full capacity of a 2,500,000-gal. engine. He also suggests the use of a portable apparatus with a single opening for discharge, consisting essentially of a Siamese nozzle, so-called, the water being carried to it by three or more lines of fire-hose. Table 14 gives the discharge of fire-hose nozzles.

SALT VELOCITY METHOD OF MEASURING FLOW.—The salt velocity method of measurement is based on the fact that salt in solution increases the electrical conductivity of water. Brine (salt solution) is injected through a system of piping and pop valves at any point in the conduit, usually at the upper end. The introduction of this brine and its passage past one or more pairs of electrodes at other points in the conduit, together with the elapsed time between points, are recorded graphically. The electrodes are so designed as to give equal weight electrically to unit areas of the pipe cross-section. The discharge $Q = V/t$ cu. ft. per sec., where V = volume of the conduit test section, cu. ft., t = time of passage of the salt solution, sec. This method, in common with all other methods of water measurement, should be used only by trained and experienced men. This salt velocity method was developed by C. M. Allen, Professor of Hydraulic Engineering, Worcester Polytechnic Institute. For a complete description of the method, see paper by Allen and Taylor, *Trans.* A.S.M.E., vol. xlv, 1923. It has been used extensively in measuring water in both closed and open conduits, and particularly in connection with field efficiency tests of water-wheels, and has been developed and improved so that it is now accepted as one of the standard methods.

THE GIBSON METHOD OF MEASURING FLOW.—The Gibson method is based on the equation of impulse and momentum applied to an enclosed column of water in motion. It is applicable in testing hydraulic power plants where the turbine is supplied with water through a closed conduit and means are available, such as turbine gates, for interrupting the flow of water. To apply the method it is necessary to measure the physical dimensions of the conduit and to obtain pressure-time diagrams, which show the changes of pressure with respect to time that occur in the conduit during and after the closing of the turbine gates. There are two kinds of such diagrams: *a. Simple Diagrams*, in which the changes of pressure at one point in the conduit are recorded; *b. Differential Diagrams*, in which the difference between the changes of pressure at two points in the conduit are recorded.

The length of conduit upstream from the point of measurement for simple diagrams or the length between the two points of measurement for differential diagrams, should, preferably, be not less than 25 ft. The conduit measurements should be made as precisely as possible. The method may be used whether the conduit is of uniform or variable cross-sectional area but, for simplicity, a section of greatest regularity and suitable length should be selected. For complete description of the Gibson method, see *Trans.* A.S.M.E., vol. xlv, p. 343, 1923. This method is applicable only to closed conduits.

SALT TITRATION METHOD OF MEASURING FLOW.—In cases where the flow is too turbulent for other methods, the salt titration method has been used. In this salt in solution is introduced at the inlet at a uniform known rate and its concentration measured at the outlet. See Salt Solution Test of Holtwood Plant, *Eng. Record*, Mar. 20, 1915, p. 358.

6. FIRE-STREAMS

FIRE-STREAM TABLES.—Table 12 is condensed from one contained in the pamphlet of Fire-Stream Tables of the Associated Factory Mutual Fire Ins. Cos., based on the experiments of John R. Freeman, *Trans.* A.S.C.E., 1889.

The pressure in the first column is that indicated by a gage attached at the base of the play pipe and set level with the end of the nozzle. The vertical and horizontal distances, in columns 2 and 3 are those of effective fire-streams with moderate wind. The maximum limit of a "fair stream" is about 10% greater for a vertical stream; 12% greater for a horizontal stream. In still air much greater distances are reached by the extreme drops. The pressures given are for the best quality of rubber-lined hose, smooth inside. The hose friction varies greatly in different kinds of hose, according to smoothness of inside surface, and pressures as much as 50% greater are required for the same delivery in long lengths of inferior rubber-lined or linen hose. The pressures at the hydrant are those while the stream is flowing, and are those required with smooth nozzles. Ring nozzles require greater pressures. With the same pressures at the base of the play pipe, the discharge of a ¾-in. smooth nozzle is the same as that of a ⅞-in. ring nozzle; of a ⅞-in. smooth nozzle, the same as that of a 1-in. ring nozzle.

The figures for hydrant pressure in the body of the table are derived by adding to the nozzle or play-pipe pressure the friction loss in the hose, and also the friction loss of a

Chapman 4-way independent-gate hydrant, ranging from 0.86 lb. for 200 gal per min. flowing to 2.31 lb. for 600 gal.

The following notes are taken from the pamphlet referred to: The discharge as stated in Ellis's tables and in their numerous copies in trade catalogs is from 15 to 20% in error.

In the best rubber-lined hose, $2\,^1/_2$-in. diam., the loss of head due to friction, for a discharge of 240 gal. per minute, is 14.1 lb. per 100 ft. length; in inferior rubber-lined mill hose, 25.5 lb., and in unlined linen hose, 33.2 lb.

Less than a $1\,^1/_8$-in. smooth-nozzle stream with 40 lb. pressure at the base of the play pipe, discharging about 240 gal. per min., cannot be called a first-class stream for a factory fire. 80 lb. per sq. in. is considered the best hydrant pressure for general use; 100 lb. should not be exceeded, except for very high buildings, or lengths of hose over 300 ft. Table 13 is computed on the basis of 14 lb. per 100 ft. of $2\,^1/_2$-in. hose with

Table 15.—Pipe Sizes for Fire Streams

(Cast Iron Pipe Handbook, 1932)

Flow given in cu. ft. per min. Figures are based on $1\,^1/_8$-in. smooth bore nozzles, playing simultaneously, and attached to 200 ft. of best quality rubber lined hose; pressures measured at hose connections. Velocity of water in pipe, approximately 3 ft. per sec. To convert to gallons, multiply figures in table by 7.4805.

No. of 1 1/8-in. Hose Nozzles	Pressure, lb. per sq. in.

250 gal. per min. flowing, as found in Freeman's tests, assuming that the loss varies as the square of the quantity, and for different diameters and the same quantity inversely as the 5th power of the diameter.

7. THE SIPHON

The siphon is a bent tube of unequal branches, open at both ends, and is used to convey a liquid from a higher to a lower level, over an intermediate point higher than either. Its parallel branches being in a vertical plane and plunged into two bodies of liquid whose upper surfaces are at different levels, the fluid will stand at the same level both within and without each branch of the tube when a vent or small opening is made at the bend. If the air be withdrawn from the siphon through this vent, the water will rise in the branches due to the atmospheric pressure without. When the two columns unite and the vent is closed, the liquid will flow from the upper reservoir as long as the end of the shorter branch of the siphon is below the surface of the liquid in the reservoir. If the water is free from air the height of the bend above the supply level might be as great as 33 ft. at sea level, and less at higher levels, corresponding approximately to the atmospheric pressure. In practice it is difficult to maintain more than about 80% of this.

If A = cross-section of the tube, sq. ft.; H = the difference in level between the two reservoirs, ft.; D = density of the liquid, lb. per cu. ft., then ADH measures the intensity of the force which causes the movement of the fluid, and $V = \sqrt{2gH} = 8.02\sqrt{H}$ is the theoretical velocity, ft. per sec., which is reduced by the loss of head for entry and friction, as in other cases of flow of liquids through pipes. In the case of the difference of level between the summit and the lower level being greater than 33 ft., however, the velocity of water in the shorter leg is limited to that due to a height of 33 ft.

8. TIDAL POWER

THE POWER OF OCEAN WAVES.—Albert W. Stahl, U. S. N. (*Trans.* A.S.M.E., xiii, 438), gives the following formulas based upon a theoretical discussion of wave motion: The total energy of one whole wave-length of a wave H ft. high, L ft. long, and 1 ft. wide, the length being the distance between successive crests, and the height the vertical distance between the crest and the trough, is

$$E = 8LH^2\{1 - 4.935(H^2/L^2)\} \text{ foot-pounds.}$$

The time required for each wave to travel through a distance equal to its own length is $P = \sqrt{L/5.123}$ seconds, and the number of waves passing any given point in one minute is $N = 60/P = 60\sqrt{5.123/L}$. Hence the total energy of an indefinite series of such waves, expressed in horsepower per foot of breadth, is

$$\frac{E \times N}{33{,}000} \quad 0.0329\frac{H^2L}{\sqrt{L}}\left(1 - 4.935\frac{H^2}{L^2}\right).$$

The utilization of the energy in ocean waves divides itself into:

1. The various motions of the water which may be utilized for power.
2. The wave-motor proper. That is, the portion of the apparatus in direct contact with the water, and receiving and transmitting the energy thereof; together with the mechanism for transmitting this energy to the machinery for utilizing the same.
3. Regulating devices, for obtaining a uniform motion from the irregular and more or less spasmodic action of the waves, as well as for adjusting the apparatus to the state of the tide and condition of the sea.
4. Storage arrangements for insuring a continuous and uniform output of power during a calm, or when the waves are comparatively small.

The motions that may be utilized for power purposes are the following: 1. Vertical rise and fall of particles at and near the surface. 2. Horizontal to-and-fro motion of particles at and near the surface. 3. Varying slope of surface of wave. 4. Impetus of waves rolling up the beach in the form of breakers. 5. Motion of distorted verticals. All of these motions have at various times been proposed to be utilized for power purposes.

The motion of distorted verticals is thus defined: A set of particles, originally in the same vertical straight line when the water is at rest, does not remain in a vertical line during the passage of the wave; so that the line connecting a set of such particles, while vertical and straight in still water, becomes distorted, as well as displaced, during the passage of the wave, its upper portion moving farther and more rapidly than its lower portion.

9. PIPE DATA *

STEEL AND WROUGHT-IRON PIPE.—For data on steel and wrought-iron pipe see pp. 5–23 to 5–68.

THICKNESS OF CAST-IRON WATER PIPES.—The specifications of the American Waterworks Assoc. (May, 1908) base the thickness of cast-iron water pipes on Brackett's formula

$$t = \{(P + P')r/3300\} + 0.25,$$

where t = thickness of pipe, in.; P = maximum static pressure, lb. per sq. in. for which the pipe is designed; P' = allowance for water ram; r = radius of pipe, in. The formula includes a large factor of safety to cover casting inequalities, water ram, and external stresses. The value of the allowance P' depends on the service. For ordinary waterworks service for pipes 42 to 60 in. diameter, a value of 70 lb. per sq. in. is sufficient. For smaller pipe the following values of P' are given by Brackett:

Diameter of pipe, in..............	36	30	24	20	16	12	10 to 3
P', lb. per sq. in..................	75	80	85	90	100	110	120

The values obtained by Brackett's formula are for ordinary conditions. For city service, the pipe should be made somewhat heavier.

Cast-iron pipe should be made of a soft and tough quality of iron, and should be tested to a pressure of twice the working pressure. It always should be coated by dipping in coal tar at a temperature of about 300° F. Table 16 gives thicknesses of cast-iron bell-and-spigot pipe for various classes of service. Table 17 gives the amount of lead required for joints in these pipes. For dimensions of cast-iron flanged fittings, see page 5–44.

LEAD AND TIN PIPE.—Weight of lead is taken 0.4106 lb. per cu. in. The safe working strength of lead is about 1/4 the elastic limit, or 225 lb. per sq. in.

Thickness of Lead Pipe, in Inches, Required for Given Head of Water is the product of the head in feet by size of pipe, expressed decimally, divided by 750.

EXAMPLE: Thickness of 1/2-in. pipe for a head of 25 ft. = 25 × 0.5/750 = 0.017. This rule corresponds to a safe working stress of 165 lb. per sq. in.

Lead Waste Pipe is made in the following sizes and weights: 2 1/2 in., 5 lb. and 10 lb. 10 oz. per ft.; 3 in., 6 lb. and 12 lb. 8 oz. per ft.; 4 in., 7 lb. 14 oz. and 16 lb. 6 oz. per ft.; 5 in., 9 lb. 14 oz. and 20 lb. 4 oz. per ft.; 6 in., 11 lb. 13 oz. and 24 lb. 2 oz. per ft.

Lead-lined Pipe is particularly adapted for use in contact with acids, mine water, salt water, or any liquid which has a corrosive action on iron pipe. See Tables 20 and 22.

For I. D. tubes, add†	1.87	1.31	0.954	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	0.008

* [illegible]

† [illegible] corresponding gage number to the weight of tube of the same outside diameter. Example: Tube, 12 in. O. D., No. 6 gage, weighs 27.71 lb. per ft.; tube, 12 in. I. D., No. 6 gage weighs (27.71 + 0.954) = 28.664 lb. per ft.

Brass and Copper Pipes, Lined with Tin or Lead are made in commercial sizes of 1/2, 3/4, 1, 1 1/4, 1 1/2, and 2 in.

Sheet Lead is rolled to any weight per square foot from 1 to 7 lb. in any width up to 11 ft. 6 in., and from 8 lb. up, 12 ft. wide. A square foot of rolled sheet lead 1 in. thick weighs approximately 59 1/2 lb.

WOOD-STAVE PIPE.—Pipe made of wood staves is extensively used on the Pacific Coast and in certain portions of the East, for conveying water, acids, paper pulp, and also substances which would react on iron or steel pipe. The pipes are made of wood staves, planed to the inner and outer radii of the pipe, with edges cut radial and tongued and grooved to make water-tight joints. The pipes are reinforced with iron or steel bands, or with a spiral of round or flat wire, the size depending upon the pressure to be sustained. Pipes up to 32 in. diameter are assembled and wound in the factory, while larger diameters are built up in the field. Table 25 gives data concerning the sizes and weights of wood-stave pipe.

Square Wood Pipe is extensively used for tanneries. It consists of square blocks with an axial hole and with tenon and socket joints. The sizes range from 4 × 4 in. outside measurement for a 2-in. diameter hole to 12 × 12 in. outside measurement with a 6-in. hole.

In all sizes of lead pipe from 3/8-in. diam. and upwards as given in Table 23 the wall thickness is such that all pipes in Class A, regardless of diameter will safely withstand a constant cold water pressure of 50 lb. per sq. in.; Class AA pipes, 75 lb. per sq. in.; Class AAA pipes, 100 lb. per sq. in.

1. GENERAL

Hydraulic turbines are divided into two general types: (*a*) reaction turbines, and (*b*) impulse turbines. Both types, however, actually involve both reaction and impulse. The two classifications are not well named, but the terms are well understood. The essential difference in the two types is that the water enters the runners of reaction turbines after only a portion of its energy has been converted into velocity; that is, it enters the reaction turbine runner under pressure. On the other hand, the water strikes the runners of impulse turbines under atmospheric pressure after all of its energy has been converted into velocity. Fig. 1 shows a hydroelectric unit comprising a reaction turbine driving a generator, and Fig. 2 a hydroelectric unit involving an impulse turbine.

The class of reaction turbine in most extensive use today is the Francis inward-flow type, shown in Fig. 1. For the lower heads, where high specific speed (see p. 2–43) is required, the propeller type, with adjustable blade (Fig. 3), (commonly known as the Kaplan type), is at the present time (1935) being extensively adopted. For all of the above types of reaction turbine, movable gates with axes parallel to the turbine shaft are used to control the flow of water to the turbine runner. The governor actuates the gates through the operating ring as indicated in Fig. 1. The water enters the volute casing from the intake passages, passes through the stay vanes, movable gates, and runner into the draft-tube through which it flows into the tail-race below the power house. The runner blades of the Kaplan type are adjusted during operation synchronously with the movable gates, with resulting high part-load efficiency. The water acts on the runner

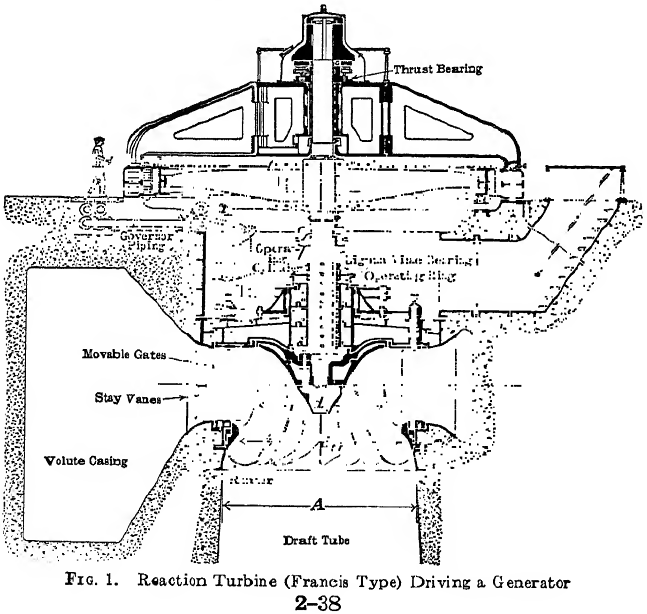

Fig. 1. Reaction Turbine (Francis Type) Driving a Generator

of the impulse turbine, Fig. 2, generally through one nozzle as indicated, although two, three, or four may be used to obtain higher speed. Where more than two nozzles are used it is necessary to adopt the vertical shaft. The power developed is controlled by actuating the needle shown in the center of the nozzle or by deflecting the stream between the nozzle and the runner.

SPECIFIC SPEED.—To compare all turbine runners directly they must be reduced to a common basis. If a turbine runner be reduced mathematically to such a size that it would develop one horsepower under a head of one foot, the speed in revolutions per minute at which it would operate under these conditions is known as its *Specific Speed.* The specific speed is the commonly-accepted basis of comparison of the performance of reaction and impulse turbine runners. Suppose a turbine operates at a speed of r.p.m. under a head of H, and that it develop power = Hp. The power developed by a turbine varies with the head and with the quantity of water flowing. The latter varies as the square root of the head. Therefore, the above turbine under a head of 1 ft. will develop

$$\text{Hp.} \times (1/H) \times (1/\sqrt{H}) = (\text{Hp.}/H^{3/2}) \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

Since the speed varies as the square root of the head, this turbine runner under 1 ft. head

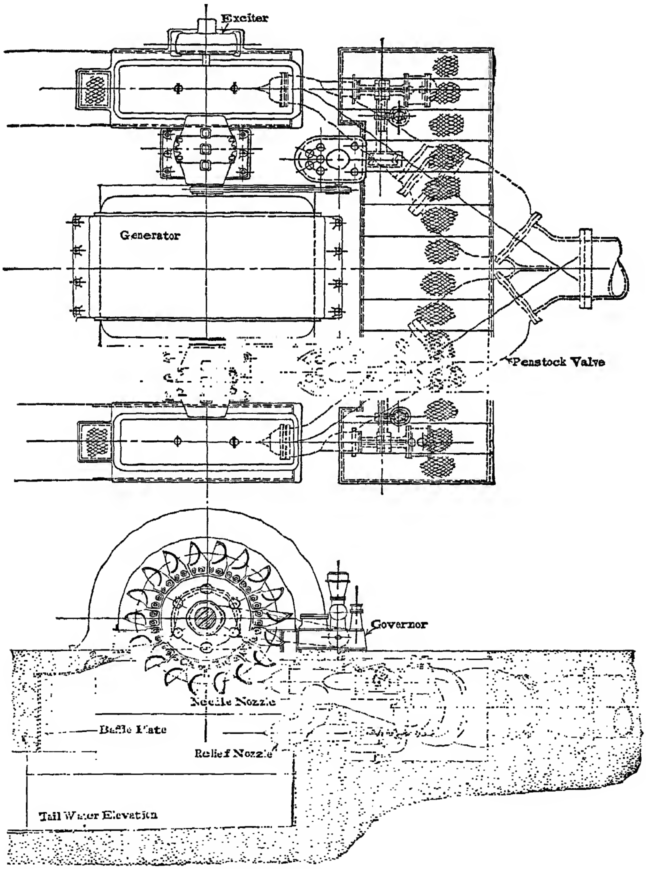

FIG. 2. Impulse Turbine

will operate at r.p.m. $\times (1/\sqrt{H})$. For a given head, the power developed varies with the area of the discharge passages, and this in turn varies as the square of the diameter. The latter varies inversely with the speed in r.p.m. That is: $\text{Hp.} \propto d^2 \propto 1 \div (\text{r.p.m.})^2$, whence $\sqrt{\text{Hp.}} \propto 1/\text{r.p.m.}$ or $\text{r.p.m.} \propto (1/\sqrt{\text{Hp.}})$ Therefore, if the runner is reduced to such a size that it will develop 1 horsepower under 1 ft. head, it will operate at a speed of

$$\text{r.p.m.} \times \frac{1}{\sqrt{H}} \times \sqrt{\frac{\text{Hp.}}{H^{3/2}}} = \text{r.p.m.} \times \frac{\sqrt{\text{Hp.}}}{H^{5/4}} = \text{specific speed} = N_s \qquad [2]$$

The head H is always measured in feet.

The horsepower referred to here is the horsepower per runner where the turbine is provided with more than one.

Specific speed is sometimes expressed as the speed at which a turbine runner would operate if reduced to such a size that it would develop one metric Hp. under one meter head.

On this basis, $N_s = 4.45 \times \text{r.p.m.} \times (\sqrt{\text{Hp.}}/H^{5/4})$ . . . . [3]

In this discussion, N_s based on 1 ft. head will be employed. Table 1 gives values of $H^{5/4}$ for values of H from 1 to 999 ft. for convenience in computing specific speeds.

SELECTION OF TYPE.—*Reaction vs. Impulse.*—From the standpoint of efficiency, it is desirable to employ the reaction type. This type is not considered suitable, however, for heads in excess of about 900 ft., and for specific speeds of less than about 12, unless the power to be developed is great, and the water is exceptionally free from abrasive matter. The curve, Fig. 4, indicates, in general, the efficiencies which have been obtained at varying values of N_s, and also indicates the dividing line between the two types of turbines. The impulse turbine efficiencies indicated in Fig. 4 do not allow for the loss in efficiency due to head lost from the center line of the nozzle to tail-water. When the head is comparatively low this loss is perceptible as the lower edge of the impulse turbine buckets must be kept well above the highest tail-water elevation. It is necessary to employ the impulse type in some instances where the head is lower than 900 ft., when the power to be developed is relatively small, as in such a case a reaction turbine (having, necessarily, a higher N_s) would operate at a speed which would be mechanically excessive.

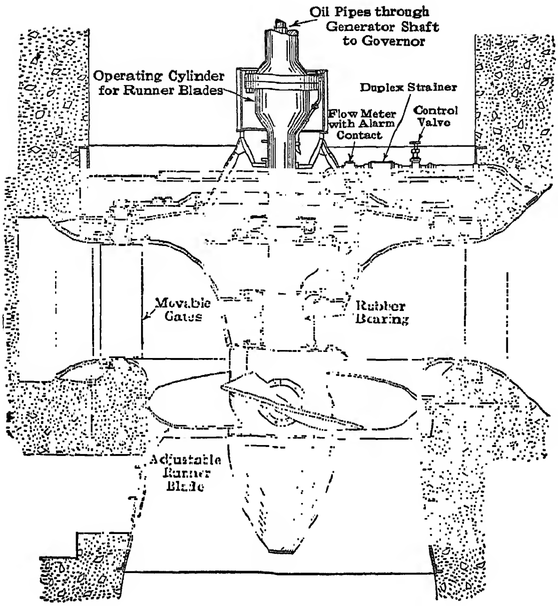

FIG. 3. Reaction Turbine, Kaplan Type

Further, the leakage losses are excessive for reaction turbines of small dimensions where the specific speed is near the dividing line. It is, perhaps, a conservative rule not to allow the speed of turbines, except those of very small capacity, to exceed 1200 r.p.m. For example, suppose it be desired to develop 300 Hp. under a head of 500 ft. For the reaction type, with the minimum value of $N_s = 12$, the resulting r.p.m. $= (12 \times 500^{5/4})/\sqrt{300} = 1640$. It is evident that these conditions call for the impluse type. Also, if the water to be used contains an excessive amount of sharp sand or other abrasive foreign matter, it is often advisable to use the impulse type, even though the other conditions point to the reaction type. This foreign matter is so much more injurious to the latter type than to the former, that the expense entailed by replacement of gates, seal rings, and runners, often exceeds any saving in first cost made by the installation of the reaction type.

SYNCHRONOUS SPEEDS.—Hydraulic turbines are generally direct-connected to alternating-current generators. It is therefore necessary for the turbines to operate at that synchronous speed which is nearest the proper speed from a hydraulic and mechanical standpoint.

The frequency of a generator = (r.p.m./60) × No. of pairs of poles on generator field.

Where a turbine drives an induction generator, the speed should be about 3% above the synchronous value.

2. REACTION TURBINES

SELECTION OF TYPE.—If the conditions outlined in the foregoing pages call for a reaction type turbine, the kind of reaction turbine to be chosen is determined by further consideration of the conditions to be met. A head between 900 and 65 ft. generally indicates the Francis type. For unit capacities above 1000 Hp. the vertical shaft arrangement, Fig. 1, should be used, unless local conditions (*e.g.* equipment to be installed in existing power plant) require a horizontal shaft. For heads above 80 to 100 ft., a metal

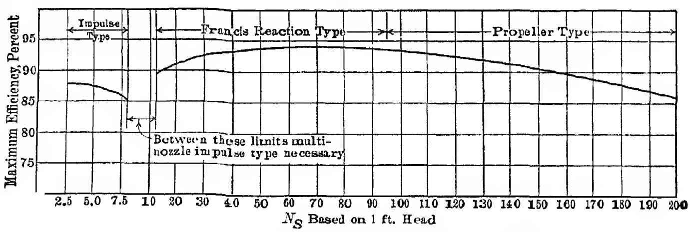

FIG. 4. Efficiency of Various Types of Turbines

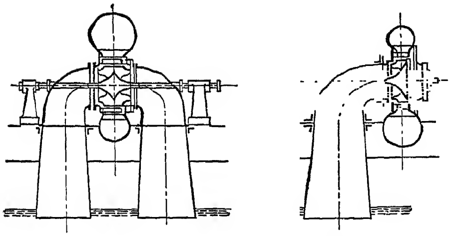

FIG. 5. Horizontal-shaft Reaction Turbine

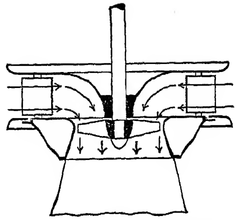

FIG. 6. Vertical-shaft Reaction Turbines

casing is used, of cast steel or plate steel, depending upon the head and size. The horizontal shaft type, Fig. 5(*a*) and (*b*), often is used for these limits of head if the amount of power to be developed is small, it having greater accessibility.

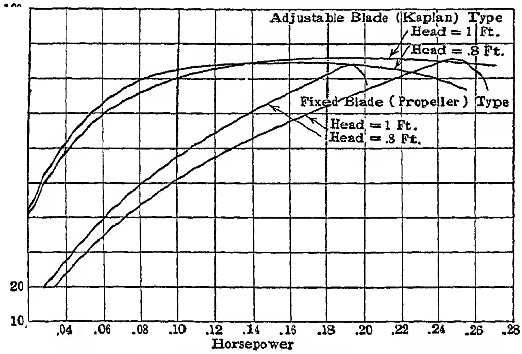

FIG. 7. Comparison of Performance of Kaplan Type and Reaction Type Turbines

Heads below about 65 ft. indicate the propeller type, either with adjustable runner blades, Fig. 3 (Kaplan type) or fixed runner blades, Fig. 6. For run-of-river installations with available head and flow varying, the Kaplan type offers decided advantages in maintaining the rated power output under reduced head, and in maintaining high efficiency under reduced flow. Fig. 7 compares performances of Kaplan type under normal and 80% of normal head, with that of fixed blade type. The marked increase in efficiency for part loads and in the power obtained under the low head are clearly shown. The fixed blade type sometimes is used where the flow and head are fairly constant, or in conjunction with one or more units of the Kaplan type. In the latter case, variations in flow are taken by the Kaplan unit; the fixed blade unit, operates at a more or less uniform load.

For heads below 20 to 25 ft., the siphon setting, Fig. 8, is advantageous. It reduces excavation costs and permits the generator floor to be set above headwater elevation. If headwater level is fairly constant, it may be possible to omit the head gates and to employ stop logs at intake for the infrequent inspections of the casing. Ejectors may be used to exhaust the air from the casing on starting the unit in operation.

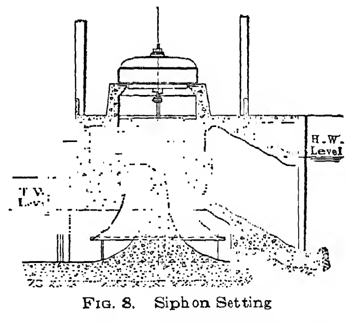

FIG. 8. Siphon Setting

The open flume setting sometimes is used for this range of heads where the power developed is small, and where minimum first cost is decisive. The turbine is completely submerged in an open flume or pit. The disadvantage of this type is the inability to lubricate the operating mechanism properly, with consequent relatively rapid wear. An important feature is the prevention of air vortices. There is no known formula for determining the amount of submergence to prevent these, as the tendency varies with different types of turbine (being greater with horizontal shaft installations) and with different designs of the same type. On this account, and due to poor lubrication, the open flume setting should be avoided where possible.

DETERMINATION OF SPEED.—The curve, Fig. 9, shows usual values of N_s which are being generally adopted at present (1935) for varying values of head H. Local requirements may call for a lower value of N_s than this curve indicates, but higher values should be avoided. The selection of any value of N_s is not only a function of the head H, but of the draft head adopted. Where, for any reason, the latter must be great, the value of N_s should be lowered to give a suitable value of σ. (See page 2–53.) As costs vary inversely with some function of the selected N_s, it is desirable to keep the latter value as high as permissible.

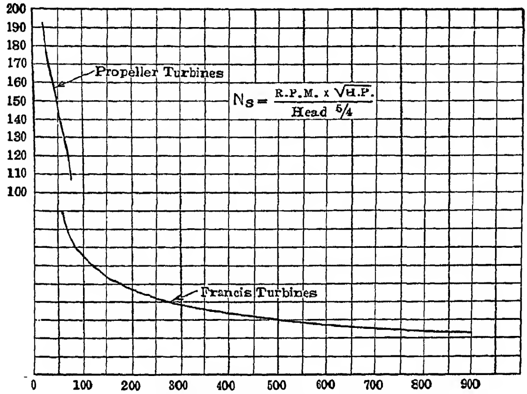

Fig. 9. Values of N_s Generally Used

NUMBER OF UNITS REQUIRED depends upon several considerations, among which are: 1. *Cost.* The cost of the turbines themselves, per Hp. developed, tends to decrease with increasing capacity up to a runner diameter of about 100 in. Above this diameter the cost per Hp. tends to increase with increasing capacity, as the weight and cost increase faster than the horsepower developed. The electrical connections, maintenance, and operating costs, however, tend to decrease with decreasing number of units. Therefore, in general, the smaller the number of units, the lower the overall cost of the development. 2. *Efficiency.* With a given specific speed, the larger the unit capacity the higher the efficiency, as indicated by formula [7]. 3. *Flow Characteristics.* If flow is widely variable, it should be possible to obtain reasonably high efficiency at the minimum value of flow. This may be effected by adopting turbines with high part-load efficiency, such that when only one unit is in operation, minimum flow conditions may be efficiently met; or by selecting a small number of large units, and one small unit of high part-load effi-

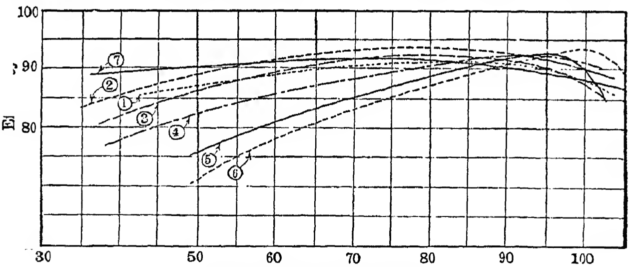

Fig. 10. Typical Characteristic Curves

ciency. The latter scheme has the disadvantage of requiring a more complex plan for operating the units for best efficiency.* 4. *Maximum Unit Capacity Available.* In line with the first consideration, cost, if there is a very great amount of power to be developed, the largest practicable unit capacities should be adopted. No limit of maximum capacity possible of the turbine proper has been reached, but the largest capacities to date (1935) are: Head 48 ft, 45,000 Hp., Wheeler Power Plant, Tennessee Valley Authority (under construction); head 55 ft., 42,000 Hp., Safe Harbor Water Corporation; head 55 ft., 66,000

* See Operating a Hydro-Electric System for Best Economy, E. B. Strowger, *Power Events*, June, 1929, published by Buffalo Niagara & Eastern Power Corp.

Hp., Bonneville Development, U. S. Government (under construction); head 89 ft., 54,000 Hp., Conowingo Development, Susquehanna Power Company; head 116.5 ft., 84,000 Hp., Dneipestroy Development, U.S.S.R.; head 520 ft., 115,000 Hp., Boulder Dam Development, U. S. Government (under construction).

VARIATION OF CHARACTERISTIC CURVES WITH N_s AND TYPE.—Fig. 10 shows a number of typical characteristic curves, plotted between efficiency and percent of rated horsepower, for various values of N_s. These curves show, starting with the lowest N_s, namely 21, how increasing N_s above a value of about 35, has the effect of reducing the part-load efficiency, this effect continuing to the fixed blade propeller type, curve 6, with $N_s = 120$.

The Kaplan type of propeller turbine, with runner blades adjustable during operation, has a very flat curve (7), with high efficiency over wide ranges of horsepower developed and quantity discharged. The part-load efficiencies are even higher than those of the low N_s Francis type turbines.

USE OF MODEL RUNNER TESTS.—The performance of model runners, if correctly interpreted, may be used as a reliable indication of the performance of large units. It is vitally important, however, that in making use of model tests, other considerations than that of the runner alone be taken into account. If the large turbine is to be installed under restricted conditions as regards design of casing and draft-tube, these conditions must be reproduced faithfully in the test of the model runner in order to obtain a prediction of the performance of the large unit. This is particularly important as regards the draft-tube if N_s is high. Hence, to apply these tests to any large installations, the latter should be provided with liberally-designed casings and with modern draft tubes (see p. 2–53.)

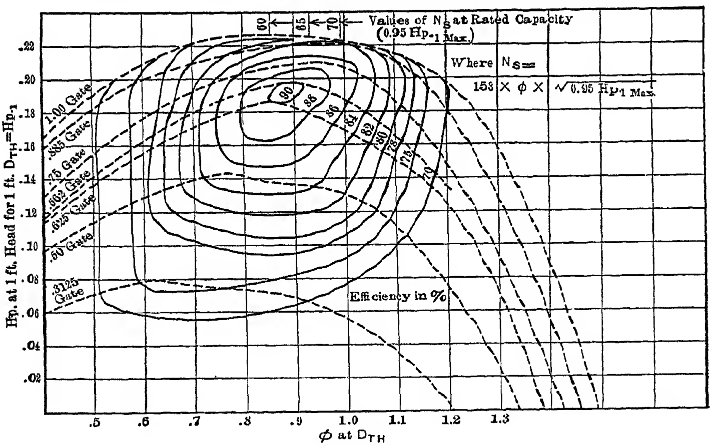

Fig. 11. Model Runner Test Curves

Assume that a water power site is to be developed where the effective head will be 100 ft., and that the unit capacity is to be 10,000 Hp. With N_s = 64, r.p.m. = $(64 \times 100^{5/4})/\sqrt{10{,}000}$ = 202.5. With a frequency of 60 cycles, 200 r.p.m. corresponds to a generator having 18 pairs of poles, and the corrected value of N_s = 63.3. Assume that the test curves shown in Fig. 11 represent performance of a model runner and draft tube that may be stepped up in dimensions for this project. It will be noted that this runner develops a value of N_s = 63.3 at ϕ = 0.891. The term ϕ(peripheral velocity in ft. per sec. ÷ $\sqrt{2gH_0}$), where g = acceleration due to gravity = 32.2 ft. per sec. per sec., and H_0 = effective head on turbine. ϕ is measured at the throat of the runner (see Fig. 3). This value of N_s is not computed at maximum power, but at 0.95 thereof, which corresponds with the rated capacity. The performance curve now may be drawn. For a value of ϕ = 0.891, the corresponding values of efficiency and horsepower, should be tabulated. The throat diameter, D_{th} (in.) of the runner under consideration =

$$(0.891 \times 1836 \times \sqrt{100})/200 = 81.75 \text{ in.}$$

Remembering that Hp. ∝ diam.² $H^{3/2}$, Hp. ∝ for the conditions under consideration = $Hp._1 \times (81.75/12)^2 \times 100^{3/2}$ Hp. = $Hp._1 \times 46{,}500$. At rated capacity as taken from Fig. 11, $Hp._1$ = 0.215, and $0.215 \times 46{,}500$ = 10,000 Hp. This agrees with the rated capacity of the turbine under consideration, thus indicating that the selected value of ϕ is correct. If the head is variable,

Hp.-efficiency curves may be drawn for the values desired by obtaining new values of ϕ and new values of $(D\text{th}/12)^2\,H^{3/2}$. If the minimum head is considerably less than the normal value, a frequent condition at low-level developments, it is desirable that the maximum power possible be developed at the low heads. This is equivalent to stating that the values of Hp._1 at higher than normal should be greater than at normal ϕ.

A complete group of curves, as shown in Fig. 11, is necessary to determine the characteristics of a Kaplan type runner. Each of these curves represents a test at a fixed blade angle. The Hp.-efficiency curve for any value of ϕ is obtained by plotting the Hp. curves for all blade angles at that value of ϕ, and then drawing an envelope curve tangent to each blade angle curve.

Increase in Efficiency with Increase in Runner Diameter.—The formula for stepping up efficiencies of model runners in order to predict that of the large prototype, as developed by Prof. L. F. Moody, has been found to be quite accurate. This formula is

$$E_1 = 1 - (1 - E)\,(D/D_1)^{1/4}\,(H/H_1)^{1/100} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [4]$$

where E and E_1 = efficiency of large and small runners, respectively; D and D_1 = the diameters, and H and H_1 = the heads acting.

RUNNER PROPORTIONS.—After determining the value of N_s and consequently the r.p.m. of a runner, it is necessary (unless the runner to be constructed is to be stepped up from a small model runner as described above), to select arbitrarily a value of ϕ for the determination of the diameter at the throat and at the vane tips. It is also necessary to select a ratio of e_1/d_{th} (see Fig. 1) in order to fix the former. The curves in Fig. 12 indicate values of ϕ_{th} (at throat), ϕ_1 (at vane tips), and e_1/d_{th} = (distributor width ÷ diameter at throat) for varying values of N_s which have been found by trial to give the most satisfactory results. These values are not to be adhered to rigidly, but are submitted as a guide. The values of ϕ_{th}, ϕ_1 and e_1/d_{th} of a model runner which may be used as the basis of construction of a larger one, fix these values in the case of the larger runner without reference to Fig. 12, except for purposes of comparison. Again, it may be necessary for draft-head reasons (see p. 2–52) to increase somewhat the value of ϕ above that indicated in Fig. 12, thus reducing the throat velocity and increasing the allowable distance that the runner may be placed above tail-water. Fig. 13 gives profiles of runners of varying values of N_s, having proportions obtained from Fig. 12, and drawn to such size that they each would develop 1 Hp. under 1 ft. head. A propeller runner also is shown.

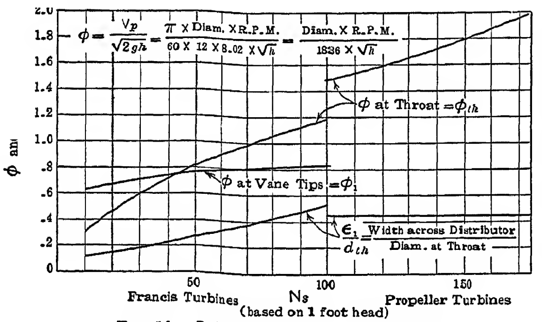

FIG. 12. Relation of ϕ_{th}, ϕ_1, e_1/d to N_s

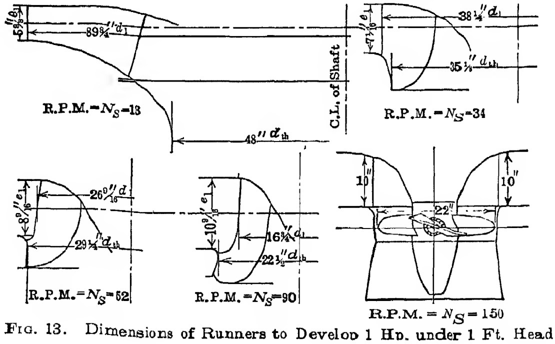

FIG. 13. Dimensions of Runners to Develop 1 Hp. under 1 Ft. Head

The N_s of these runners is therefore synonymous with the r.p.m. as noted. These profiles indicate clearly the desirability of increasing N_s as a means of reducing the cost of the unit.

METHODS OF INCREASING POWER UNDER REDUCED HEAD CONDITIONS.—A characteristic of the majority of low-head developments is the marked reduction in head available with increased flow conditions during flood seasons.

a. For heads above allowable values for propeller type (about 65 ft.). Under these circumstances it is desirable to adopt a runner which develops under higher than normal values of ϕ, a greater power than that at the normal ϕ. As a means of further increasing the power available during low-head conditions, the ejector turbine (Fig. 14) has been devised by L. F. Moody which uses the surplus water as a means of increasing the effective head on the turbine. Fig. 15 shows the increase in power which results from the use of this device. The decreased efficiency during the operation of the ejector as noted is of no consequence since the ejector is used only when surplus water is available. It will be noted that where the head is 0.8 of the normal value, the power with the ejector in operation is very nearly that developed by the turbine at normal head with the ejector closed. The ejector consists of openings provided immediately below the turbine runner from the casing to the draft-tube, which openings are controlled by a cylindrical gate through rods passing up to the operating deck of the turbine.

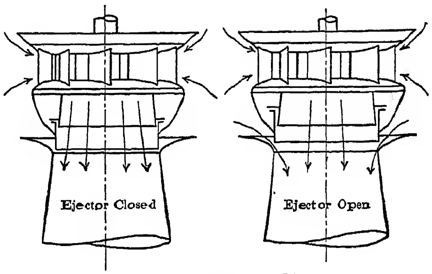

FIG. 14. Ejector Turbine

O. G. Thurlow, Chief Engineer of the Alabama Power Co., has devised a novel means of suppressing the tail-water elevation during flood condition by utilizing the waste water flowing over the spillway. (See J. A. Sirnit, Hydroelectric Power Plant Design, *Trans*. A.S.M.E., xliv, 1922.) This device requires a relatively large amount of waste water, but under these conditions is very effective.

b. For heads permitting use of propeller type (below 65 ft.). Under these conditions the adjustable runner blade or Kaplan type of propeller turbine is decidedly the best. Fig. 7 shows the gain in power as compared to the fixed blade propeller type

3. OUTLINE OF THEORY OF REACTION TURBINE RUNNERS

The design of reaction turbine runners has as its basis the theorem, "The power of a turbine in steady motion equals the angular velocity multiplied by the change of angular momentum experienced by the mass of water flowing in a unit of time in its passage through the turbine." This principle, probably first discovered by Leonhard Euler in 1754, is known as the Eulerian Theorem.

Notation.—All velocities, except where noted, are in ft. per second. Let C_0 = absolute velocity of water leaving movable gates; C_1 = absolute velocity of water at radius r_1, ft.; C_2 = absolute velocity of water at radius r_2, ft.; U_1 = absolute velocity of turbine runner

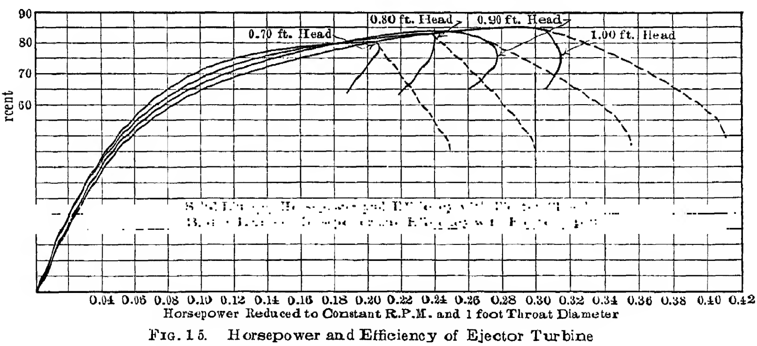

FIG. 15. Horsepower and Efficiency of Ejector Turbine

at radius r_1, ft.; U_2 = absolute velocity of turbine runner at radius r_2, ft.; CU_1 = tangential component of $C_1 = C_1 \cos \alpha_1$; CU_2 = tangential component of $C_2 = C_2 \cos \alpha_2$; C_{m1} = radial component of $C_1 = C_1 \sin \alpha_1$; C_{m2} = radial component of $C_2 = C_2 \sin \alpha_2$; w_1 = velocity of water at r_1 relative to runner; w_2 = velocity of water at r_2 relative to runner; ω = angular velocity of turbine runner, radians per second; M = mass of water discharged by runner per sec. = W/g; Q = quantity discharged, cu. ft. per sec. W = weight of water flowing per sec., lb.; 62.4 = weight of 1 cu. ft. of water, lb.; g = acceleration due to gravity = 32.2 ft. per sec. per sec.; H = head acting on turbine runner; e = hydraulic efficiency of turbine runner; K_1 = moment arm of C_1, ft.; K_2 = moment arm of C_2, ft.

Fig. 16, wherein this theory is applied to the design of a Francis type turbine, shows angular moment at entrance to runner to be $K_1 \times C_1$ and at exit $K_2 \times C_2$.

Power delivered by water to turbine $= P = \omega \times M \times (K_1 C_1 - K_2 C_2)$

$$= \{(\omega \times Q \times 62.4)/g\} \times (K_1 C_1 - K_2 C_2) \quad [5]$$

By similar triangles, $K_1/r_1 = CU_1/C_1$ and $K_2/r_2 = CU_2/C_2$.

Therefore, $$\text{Power} = \{(\omega Q \times 62.4)/g\} \times (r_1 CU_1 - r_2 CU_2) \quad [6]$$

Since (angular velocity × radius) = linear velocity at outer end of radius, $\omega r_1 = U_1$, and $\omega r_2 = U_2$,

and $$P = \{(Q \times 62.4)/g\} \times (U_1 CU_1 - U_2 CU_2) = Q \times 62.4 \times H \times e, \quad [7]$$

whence $$gHe = U_1 CU_1 - U_2 CU_2 \quad [8]$$

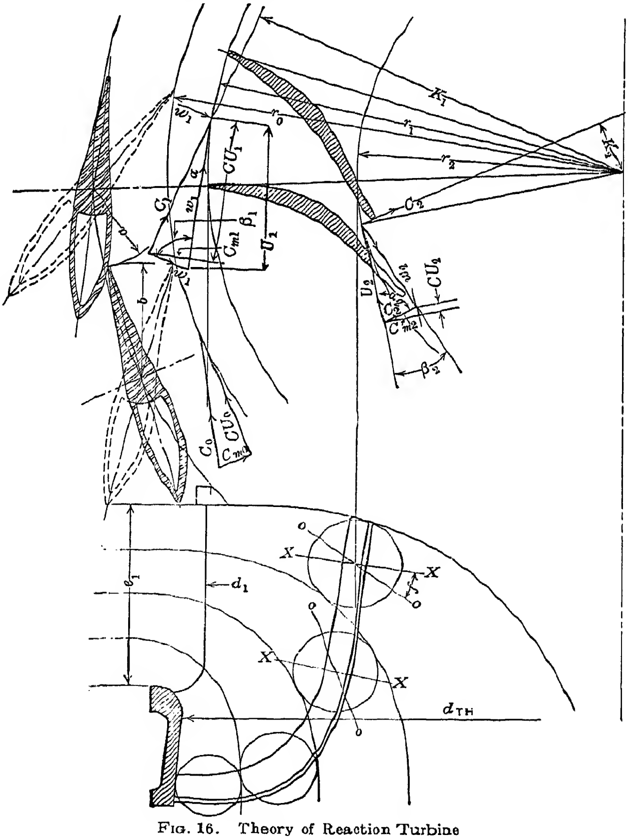

FIG. 16. Theory of Reaction Turbine

Equation [8] may be used as the basis of turbine runner design, for determining the entrance and discharge angles of the runner vanes and also of the movable gates at the entrance to the runner.

Referring to Fig. 17, it will be noted that, except at very low values of N_s, there is a whirl component CU_2 in the direction of rotation at maximum efficiency. At rated capacity, however, there is a whirl component against the direction of rotation for values of $N_s < 50$. The curves shown in Fig. 17 are the results of observations of the flow for turbines of efficient design.

With the controlling data given, *i.e.*, the horsepower to be developed, the effective head, and the r.p.m., the value of N_s may be calculated (see p. 2–39). For the latter value, the values of ϕ_1, ϕ_{th} and e_1/d_{th}, may be found from Fig. 12. For the value of specific speed under consideration, an inspection of the curves in Fig. 10 will show the approximate percentage of the rated turbine capacity at which maximum efficiency will occur. The maximum efficiency which may be attained may be estimated from a consideration of the dimensions of the runner (see formula [4]) and from Fig. 4. The quantity discharged at maximum efficiency may be determined by the formula

$$Q = (\text{Hp.} \times 550)/(H \times 62.4 \times E) = \text{Hp.}/(0.1134 \times H \times E), \quad . \quad . \quad . \quad [9]$$

where H = head acting on turbine, and E = efficiency.

PROFILE OF RUNNER VANES.—The profile of the runner vanes, including the runner band and runner crown, may be laid down as indicated in Fig. 16. The curvature from the lower distributor to the throat of the runner should have as large a radius as practicable, and the flow from the runner band into the top of the draft-tube should be without any sudden break. The shape of the profile should be such as to give sufficient depth to the vanes for proper guidance and flow of the water, without, at the same time, resulting in high friction losses. In particular, with the higher speed runners, where the profile of the vanes at outflow is not at right angles to the direction of flow, the runner should be subdivided into several sections by means of equal quantity flow lines, and the design in each one of these subdivisions should be treated separately. Table 2 may be used as an approximate guide for the number of runner vanes.

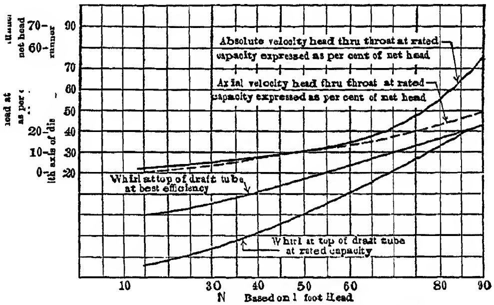

Fig. 17. Amount of Whirl in Draft Tubes

For the specific speed under consideration the amount of whirl in the draft-tube at best efficiency may be taken from Fig. 17. This angle of whirl has been determined by test to be approximately constant at all distances from the center-line of the shaft. Considering the upper subdivision of the runner in Fig. 16, where $(90° - \alpha_2)$ is the angle of whirl, it is seen that $CU_2 = C_{m2} \tan (90° - \alpha_2)$. C_{m2} is the velocity of the water in a vertical plane passing through the axis of the runner, and is determined by the area between the flow lines at radius r_2, allowance being made for the area occupied by the runner vanes. It is then possible to obtain the term CU_1 from the general equation

$$gHe = U_1 CU_1 - U_2 CU_2, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [10]$$

since all other terms are known. C_{m1} may then be found from the area at the intake to the runner. The values w_2, C_2 and C_{m2} in the plan view of Fig. 16 should be considered as lying in the direction of flow, that is in direction OO. In determining β_2 on the line XX which is at right angles to the surface of the runner vane at outflow, the outflow triangle should be constructed on the basis that C'_{m2} (in the direction XX) $= C_{m2} \times \cos f$.

GATES.—After determining the number of gates and the distance between the center lines of the gate shanks and of the turbine shaft, the radius r_0 may be determined as

Table 2.—Approximate Number of Runner Vanes

	Francis Type					Propeller Type		
N_s.	12–18	18–30	30–45	45–70	70–100	100–130	130–175	175–200
No. of wheel vanes.	19	18	17	16	15	6	5	4

being the radius at which the water leaving the two sides of any gate converges, forming a solid mass. The number of gates is generally between 12 and 20, the number being smaller for mechanical reasons for turbines of smaller proportions. There is no well-defined relation between the number of gates and the value of N_s. From the relation $r_1CU_1 = r_0CU_0$, the value of CU_0 (Fig. 16) can be determined. The value of C_{m0} obviously can also be determined, and hence the value of C_0; the angle and opening of the gates necessary may be determined from the latter value. Additional gate opening must be provided for that portion of the performance curve (see Fig. 10) between maximum efficiency and maximum power. Maximum designed horsepower should be about 5 or 6% greater than the rated or guaranteed value. This margin is necessary to insure the attainment of the rated horsepower under test, to allow for variations between design and actual construction, and for slight inaccuracies in calculations. To design for maximum efficiency at too low a percentage of the rated horsepower is to risk failing to attain the rated capacity. For the application of rational theory to the design of propeller type runners, see W. Spannhake, Problems of Modern Pump and Turbine Design, *Trans.* A.S.M.E., vol. lvi, p. 225, 1934.

4. FEATURES OF TURBINE DESIGN

CASING.—The volute type of casing universally is accepted as the most efficient. The areas of the casing passages surrounding the stay ring (Fig. 18) should be determined on the basis that $CU_x \times r_x = J$, where CU_x = tangential component of velocity of any filament, at radius r_x of filament, measured from the center-line of the shaft, and J = a constant. This results in increasing velocity as the water passes around the casing toward the baffle vane of the stay ring. Casing areas frequently are designed on a basis of constant velocity; the excess area will be occupied by eddies, since the velocity actually increases in accordance with the above law. Hence, an attempt to prevent excessive friction loss may lead to excessive eddy loss. The velocity head at the intake to the casing proper should be roughly 2 to 3% of the effective head on the turbine. This value may, however, be increased without appreciable loss.

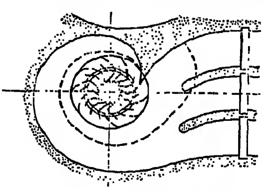

FIG. 18. Volute Casing

STAY RING.—The angle of the stay vanes at the intake may be determined as follows:

The tangential component of velocity at the intake to the vanes is equal to $J/r_g = CU_g$, the constant J being same as that used in the design of the casing and CU_g and r_g being, respectively, the tangential component of velocity at, and the radius of, the stay ring at intake. The radial velocity component obviously can be determined from a consideration of the quantity flowing and the radial inlet area to stay ring. From these two values the proper entrance angle for the stay vanes may be determined. For the true volute casing this angle should be constant for all vanes. The movable gates should be so located in conjunction with the stay ring that the water will have a smooth passage inward at the gate opening giving best efficiency. Attention also should be given to the stream shape at full gate. At low gate openings there is necessarily a certain amount of impact loss due to the gates not coinciding with the stay vanes. This impact is slight, however, since the velocity of flow between the stay vanes and at the outer ends of the gates is low under these conditions.

Turbines of large and medium size often are provided with casings of the partial volute type, due to necessity for reduced unit spacing. The angle of the stay vanes at the upstream portion of such casings is determined by model tests. An efficient angle for these vanes, with the usual design of casing, is 30° with the radial. Usual practice is to provide half as many stay vanes as there are gates.

THRUST BEARINGS.—This part of the hydro-electric unit invariably is supplied with the generator. Two types are in general use, namely, the Kingsbury and the General Electric spring type. Both operate in oil baths under atmospheric pressure, and depend on the viscosity of the oil carrying a wedge-shaped oil film between the rotary and stationary surfaces. Most recent practice (1935), particularly with the larger units, is to have the thrust bearing located below the generator and combined with a guide bearing. This arrangement results in the supporting beams being of reduced length and weight, and in general does away with the need of an upper generator guide bearing.

RUNAWAY SPEED.—Both the generator and turbine parts should be designed safely to withstand the full runaway speed of the turbine, with maximum gate opening and no

load on the generator. For impulse wheels the runaway speed is generally 80% to 90% above normal speed. For Francis turbines of low specific speed it is 65% to 80%; for high specific speed Francis turbines, 80% to 90%, and for the Kaplan type it may be as high as 130% above normal speed. Runaway speeds should be based on the maximum operating head, rather than the normal value.

COMPUTATION OF LOADS ON THRUST BEARINGS.—Allowance must be made for the weight of the turbine runner, turbine shaft, and the amount of hydraulic thrust on the turbine runner in the design of the thrust bearing of the vertical-shaft single-runner turbine. This thrust-bearing also carries the weight of the generator revolving parts. The weight of the turbine shaft readily may be computed. A rough idea of the weight of any Francis runner may be obtained by multiplying the cube of the throat diameter in feet by the constant 35. This applies to cast-iron or cast-steel runners with the vanes and hubs cast integrally. For propeller-type runners with fixed blades, the constant may be taken as 12; for Kaplan-type runners, as 22. This method of determining the weights of a runner, while not accurate, may be sufficiently close for determining the load on the thrust bearing, as the largest factor dealt with is generally the hydraulic thrust. Consequently, a comparatively large percentage of error in the weight of the runner has no great effect on the total estimated thrust-bearing load allowance.

The computation of hydraulic thrust on Francis runners, although somewhat complex, is subject to analysis. In carrying out this process it is necessary to take into account the pressure between the movable gates and the runner; the seal design, and area; the method of venting, and proportions of the runner. Fig. 19 gives a curve for computing the thrust on runners of varying specific speeds, where the runner is vented through a passage in the head cover leading to cored passages through the runner hub.

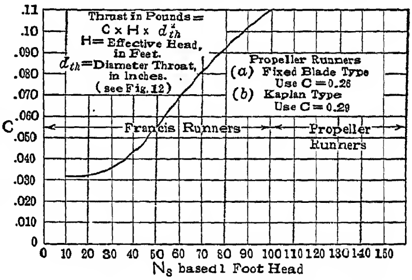

FIG. 19. Thrust on Runners of Varying Specific Speeds

In allowing for the load on the thrust bearing, the weight of the turbine runners theoretically should be reduced by the amount of its loss of weight in water. Actually, however, this reduction of weight and of the load on the bearing is neglected.

RUNNER LOSSES.—Impact and eddy losses in the runner at low gate openings are unavoidable, since the vanes of a Francis runner cannot be made movable. Friction losses can be reduced to a minimum by proper finish of the runner vanes, by proper selection of the number of runner vanes and the amount of vane surface.

The impact and eddy losses in Kaplan runners are reduced effectively by the adjustment of the runner vanes during operation to suit the gate opening. The most serious loss to contend with in this type of runner is that due to friction on the vane surfaces caused by the necessarily high values of ϕ, and resulting high relative velocities. On this account, the proper finishing of the vane surfaces is extremely important, and recourse to machine finishing is frequent.

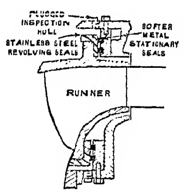

FIG. 20. Labyrinth Seals

Leakage loss around a Francis runner is greatest for low values of N_s, and *vice versa*, since this varies with a function of ϕ/N_s on a basis of uniform seal clearances and design of seals. This loss effectively can be reduced, theoretically, by using labyrinth seals. In practice, elaborate designs of this type of seal are not in wide use, due to the destructive effects of contact between the rotating and stationary seals caused by bearing wear or incorrect alignment. Present practice (1935) for large turbines of low specific speed embodies the use of rotating seal rings on the runner, preferably of stainless steel, in conjunction with stationary seals of a dissimilar softer metal. Very small clearances are used with this design, as indicated in Fig. 20, and if actual contact does occur, the softer metal wears away locally with no injurious generation of heat.

The use of stationary and revolving seals of steel is not good practice, as contact results in generation of excessive heat with consequent tearing, rolling, and welding of the metal.

The friction of the water surrounding the runner against the rotating external surfaces of the runner causes a loss known as disc loss. This may be maintained at a minimum

by finishing external runner surfaces as smoothly as possible, and by reducing the space between the runner and adjacent parts to the lowest practicable value. This loss, like loss from leakage, is greatest at low values of N_s. Experiments which have been made on machined brass discs give a value of K of 0.000,000,000,413 in the formula $\mathrm{Hp}._{df} = KD^5N^3$, where $\mathrm{Hp}._{df}$ = horsepower loss due to disc friction, D = diameter of disc, or runner, ft.; and N = revolutions per minute. This formula takes care of the loss on both sides of the disc. No experiments have been made in this connection on turbine runners but the formula may be applied thereto for comparative purposes. This loss is constant at all loads, provided the speed is constant, and, of course, affects the efficiency at part load to a greater extent than at full load. The experiments on brass discs, cited above, indicated greater loss when the disc was in a large chamber than in a restricted chamber with smooth surfaces close to the disc. Therefore, less disc loss is encountered in a turbine when the stationary surfaces are smooth and are in close proximity to the external surfaces of the runner.

The practice of providing ribs between the head or side cover and the turbine runner is bad, as these ribs merely cause eddies to be set up between them. Such eddies absorb more energy than a large body of water surrounding the runner will absorb if allowed to rotate freely. It is worthy of note that the rapidly mounting leakage and disc losses at the low values of N_s form the economic reason for changing from the reaction to the impulse type of turbine for values of N_s lower than about 12.

WATER PASSAGES.—It is important that all water passages, from intake to tail-race, receive attention, as an undue loss at any point between these limits may result in poor plant efficiency even though the turbine efficiency be exceptionally high. The velocity through the racks at the intake to the penstocks should be not more than from 2 to 3 ft. per second, as the loss there may be a perceptible proportion of the total head when the latter is low. The spacing of the rack bars should be as wide as possible and should be governed by the minimum opening between the turbine runner vanes. A well-proportioned bell-mouth should be provided to lead the water to the penstocks.

The head gate guides should not offer obstruction to flow, and the gates, when open, should be entirely out of the path of the flowing water. The gates should be as large as practicable to reduce to a minimum the number of supporting piers and the losses caused thereby. With long penstocks a careful balance should be made between the initial cost of various diameters and the loss of revenue due to corresponding penstock losses. The question of pressure changes and regulation also must be considered here (see p. 2–55). Attention should be given to the excavation of the tail-race at the discharge from the draft-tubes to prevent undue loss from unnecessarily raising the tail-water level.

CAVITATION.—In any water passage, not occupied by steadily flowing water, eddies of rapidly whirling water are formed. When the head or pressure, acting on this water passage, is reduced to that of vapor pressure (about 1.25 ft. above absolute zero pressure at the usual water temperature), vortices exist in these areas. Voids or cavities form in the center of the vortices, causing what is known as cavitation. Under such conditions, slight changes in static pressure or in velocity of flow, with resultant changes in pressure, cause the alternate formation and collapsing of these cavities. The latter phenomena are accompanied by intense local water hammer, with the formation of high local momentary pressure. If these cavities collapse on the surface of runner blades or draft tubes, the pressure generated tends to enter the microscopic cracks, causing *pitting*.

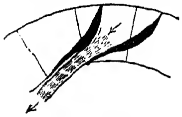

Fig. 21. Cavitation

It thus is important to so design all water passages as to avoid areas where eddies tend to form, as indicated on the back of the runner vane in Fig. 21, and to place the runner sufficiently close to tail-water level. Pitting practically always occurs on the back or underside of the vanes of vertical-shaft type turbines, as this is the low pressure side. The face of the vanes, which receives the reactive force in the form of higher pressure, is relatively much less susceptible to pitting.

High head, low specific speed turbine runners, are, in general, less susceptible to cavitation than are high specific speed, low head runners. Of all types, propeller runners are most susceptible, due to their high relative velocity and small blade area.

ALLOWABLE HEIGHT OF TURBINE ABOVE TAILWATER is one of the most important dimensions in power-house design. Numerous installations exist which have been all but ruined by fixing the runner at an excessive distance above tailwater. As a result, in such cases, excessive pitting and vibration have occurred, with heavy maintenance costs and undue limitations in power developed. Although a given turbine, operating under a high head, must be placed closer to tailwater, than when operating under a low head, it is the low head plants, *i.e.*, below about 60 ft., that are most often in difficulties,

due to excessive draft head. This is due to the use of higher specific speeds with higher relative velocities at the low heads.

L. F. Moody, in a paper at 3d American Hydro-electric Conference, Engrs. Club of Philadelphia, Mar. 10, 1925, presented formula [11] for the absolute pressure at the point of minimum pressure on the discharge side of the runner when a turbine is in operation.

$$H_m = H_a - H_s - \{(E_d C_2^2/2g) + K_c H\}, \quad . \quad . \quad . \quad . \quad . \quad [11]$$

where H_m = absolute pressure at point of minimum pressure for discharge side of runner; H_a = atmospheric pressure head at elevation of runner above sea level, ft.; H_s = static draft head or elevation of runner above tail-water, measured at the throat of a Francis runner, and at the center line of the blades of a propeller runner, ft.; E_d = draft tube efficiency; C_2 = absolute discharge velocity from the runner, ft. per sec.; H = total effective head on the turbine, ft.; K_c = cavitation coefficient.

If we combine $\{(E_d C_2^2/2g) + K_c H\}$ into a single term σH (Dr. Thoma's notation) we have $H_m = H_a - H_s - \sigma H$, or $H_s = H_a - H_m - \sigma H$.

Therefore,

$$\sigma = (H_a - H_m - H_s)/H \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [12]$$

The value H_m must be not less than the vapor pressure of water at the temperature existing. The absolute value of H_m varies within narrow limits, and virtually is always between 0.50 and 1.40.

The determination of H_s by this formula requires a value of σ for the particular specific speed, runner and draft tube design under consideration. Therefore, for the exact determination of σ, cavitation tests of a model, which is a small reproduction of the turbine to be used, are necessary. These tests are not required, however, where it is practicable to provide an ample margin in the value of σ selected. High head installations permitting very low values of σ, and very low head installations, come under this classification.

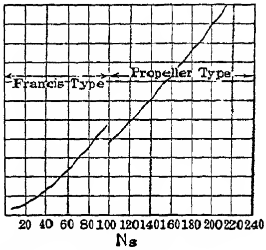

FIG. 22. Relation of σ and Specific Speed

The curve drawn between σ and specific speed, Fig. 22, is based on usual practice. It may be used as a general guide in the absence of cavitation tests. These, however, should be made for confirmation if the propeller type of turbine is used for heads above 30 ft., particularly if local conditions require the use of a low value of σ.

DRAFT TUBES permit the conservation of potential energy referred to tailwater, thus allowing the runner (when the value of σ permits) to be placed some distance above tailwater level. Draft tubes also serve to regain most of the kinetic energy in the water leaving the runner, thus making possible good efficiencies with high outflow velocities from the runner. Inefficient draft tubes have the doubtful virtue of permitting runners to be placed at a higher elevation of tailwater than otherwise would be possible without pitting, this protection of the runners being necessarily accompanied by loss of efficiency of the turbine as a whole.

Two general types of draft tubes are in use, the symmetrical and elbow types. The symmetrical type may be in the form of a straight cone, generally of steel plate, or of the

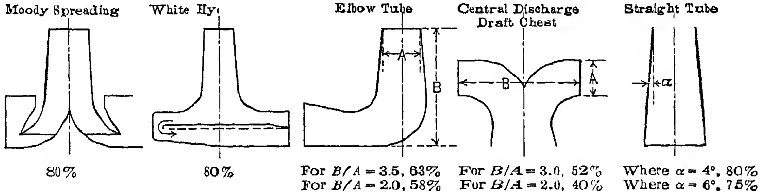

FIG. 23. Types of Draft Tubes

Moody spreading type or the White hydraucone type. All of these symmetrical tubes are capable of developing high efficiency if correctly designed. The elbow type for vertical turbines has, of late years, been developed to high efficiency. Fig. 23 shows the forms mentioned; also the central discharge draft tube, which is a form of the elbow tube.

For the elbow type, B/A should not be less than 2.00; for the central discharge draft chest, not less than 4.0 for good efficiency; for the straight conical tube α should not be greater than 6 to 7 deg.

5. TURBINE TESTS

THE TESTING OF HYDRAULIC TURBINES to determine their efficiency involves the measurement of the work done by the water on the turbine, or the water horsepower, and of the mechanical work done by the turbine, or the developed horsepower.

$$\text{Water horsepower or W.Hp.} = (Q \times 62.4 \times H_0) \div 550 = 0.1134 \times Q \times H_0,$$

where Q = cu. ft. of water passing through the turbine, per second, and H_0 = effective head, ft., acting on the turbine.

Q and H_0 may be measured as discussed below.

Developed horsepower or D.Hp. = $2\pi GAN/550$, if measured by an absorption dynamometer (generally a Prony friction brake), where G = force, lb., exerted by turbine at end of brake arm of length = A, ft., and where N = r.p.m./60.

Developed Hp. = (kw. developed by generator) ÷ (generator efficiency), where the turbine is, as is generally the case, connected directly to a generator. The method of arriving at D.Hp. in this case is described more in detail below. Turbine efficiency is, of course, D.Hp./W.Hp.

See Test Code for Hydraulic Power Plants and Their Equipment, approved by A.S.M.E., 1927, and later editions.

MEASUREMENT OF POWER OUTPUT.—For turbines direct-connected to electrical generators the power output of the turbne may be measured as provided below:

When practicable, the generator is to be separately excited during both turbine and generator tests and the excitation loss is not to be included in computing the generator efficiency. It is, therefore, also be be omitted in computing the turbine output during the turbine test. When determined by the separate-loss method, the generator efficiency in the case of polyphase alternators, when separately excited, is to be taken as

$$\frac{(\text{Kilowatt output at generator terminals})}{\begin{pmatrix}\text{Kilowatt}\\ \text{output}\end{pmatrix} + \begin{pmatrix}I^2R\\ \text{armature}\end{pmatrix} + \begin{pmatrix}\text{Open circuit}\\ \text{core loss}\end{pmatrix} + \begin{pmatrix}\text{Stray load}\\ \text{losses}\end{pmatrix} + \begin{pmatrix}\text{Generator wind-}\\ \text{age and friction}\end{pmatrix}},$$

all losses being expressed in kilowatts.

Stray load losses are to be determined in accordance with Paragraph 458 of the Standardization rules of the A.I.E.E.

MEASUREMENT OF POWER INPUT OR WATER HORSEPOWER.—The effective head on the turbine is to be taken as the difference between the elevation corresponding to the pressure in the penstock near the entrance to the turbine casing, and the elevation of the tail-water, the difference being corrected by adding the velocity head in the penstock at the point of measurement, and subtracting the residual velocity head at the point of measurement in the tail-race. When turbines are set in an open flume, the head is measured by gages located immediately above the center of the turbine and by gages in the tail-race. The effective head on such a turbine is to be taken as the difference between the elevation of the free water surface immediately above the center of the turbine and the elevation of the tail-water, the difference being corrected by subtracting the residual velocity head at the point of measurement in the tail-race.

MEASUREMENT OF QUANTITY OF WATER.—The description of the various methods that may be used, *i.e.*, by weir, salt-velocity method, Pitot tube, etc., are of too great length for reproduction here. Reference is made to the test code. See also *Trans.* A.S.M.E., xlv, 1923, for description of salt-velocity method and of Gibson method. See also p. 2–28.

6. SPEED REGULATION OF HYDRAULIC TURBINES

TURBINE GOVERNORS.—A governor designed for the automatic speed regulation of a hydraulic turbine is not as simple as one for the regulation of a steam engine. The inertia, friction, and hydraulic load acting against the movement of the turbine gates necessitate the introduction of a force external to, but controlled by, the governor for overcoming these resistances. A pump generally is used to force oil under pressure into one or two operating cylinders which actuate the turbine gates.

Fig. 24 is a diagrammatic sketch of a turbine governor. When an increase in speed takes place, the revolving flyballs T cause the right-hand end of the lever L to move upward, and open the ports of the governor valve, thus admitting oil under pressure from A to C and simultaneously connecting B with D. A gate-closing movement of the piston of the operating cylinder results, continuing until the restoring rod E has raised the left-hand end of the lever L sufficiently to close the ports of the governor valve

by lowering the right end of L. During the above operation the right end of L' may be considered as fixed. This leaves the unit at a higher speed than the normal value, but with the ports of the governor valve momentarily closed and the gates momentarily stationary. The spring F, however, is compressed since the left end of L' has moved upward from its original position. This compression causes the lever L' now to move downward slowly at the left end at a rate determined by the dash pot by-pass, L', for the time being, turning about a pivot formed by the upper end of E. This results in an upward movement of the right end of L with consequent closing movement of the turbine gates. The load on the turbine now being steady, the closing movement of the gates results in a reduction in speed until the spring F has reached its normal position, which is necessarily accompanied by normal speed and closed ports in the governor valve. Thus, following a change in load, the functioning of the governor is divided into two distinct processes. The first involves the movement of the gates to supply or cut off the necessary amount of hydraulic energy to suit the new load; the second involves the restoration of speed to the normal value necessitating an additional (but small) movement of the gates.

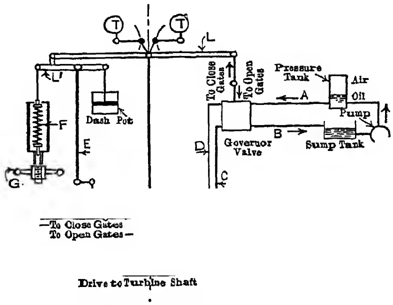

FIG. 24. Diagram of Hydraulic Turbine Governor

The hand wheel G permits the case containing spring F to be raised or lowered, and forms a means of controlling the normal speed of the unit.

DETERMINATION OF GOVERNOR CAPACITY.—This is a function of the hydraulic load on the movable gates, considering all positions of opening, with an allowance for friction and for the power required to accelerate the moving parts. To make a close determination it is necessary to have detailed data relative to the proportions of the turbine and gates. Not only does the relation between the runner diameter and gate circle diameter affect the governor capacity, but the number of gates, their proportions, height, and angular turn as well. The curve, Fig. 25, will serve as a very approximate means of determining the governor capacity required for the movement of the turbine gates. This curve is plotted between unit governor capacity and specific speed. There is indicated in this figure the formula for arriving at the approximate governor capacity for any given conditions of head and N_s. The values for very large turbines tend to be materially smaller than this curve indicates, due to relatively less friction and large number of gates used.

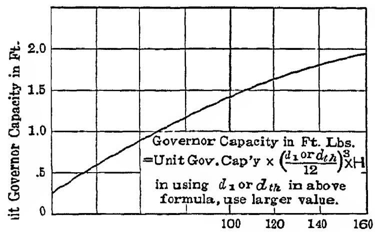

FIG. 25. Governor Capacity Required

The above curve is for use where the operating mechanism is lubricated, as on the outside type (Fig. 1). When the mechanism is submerged, and is lubricated by water only, the values from the above curve should be increased by about 1.25. This curve does not include allowances for relief valves, nor for capacity required for runner vanes of Kaplan type turbines.

REGULATION FOLLOWING SUDDEN LOAD CHANGES.—It is evident that regulation by means of a governor, similar to that described above, is one of degree only, since a change in speed is necessary before the governor will act. The inertia of the water in the turbine water passages, including penstock and draft-tube, prevents a prompt increase or decrease in the energy supplied to the turbine as called for by the governor, thus aggravating the speed change which occurs. The change in speed as the result of a given sudden load change is a function of (1) the inertia effect, or WR^2 of the rotating element of the unit; (2) the inertia effect of the water passages; (3) the relation between time and gate movement.

It should be noted that with the above values and relations fixed, and neglecting the effect of lost motion, all makes of governor will give a uniform degree of speed regulation.

Let N = r.p.m. of unit before gate movement. This is generally the normal or the synchronous value at full load, and from 3% to 5% higher at no load. This difference

in speed is known as the inherent speed change, and is necessary in order that the percentage of load on turbines operating in parallel may be maintained by the governors at about the same value. Therefore, N for loads going off is lower than for loads going on; however, since the term speed regulation generally relates to the percentage of momentary speed change succeeding a load change, the fact that the speed returns to a value of N which is slightly higher or lower than N before the load change may be neglected.

Let N_1 = maximum or minimum r.p.m. succeeding the load change; WR^2 = product of weight of revolving parts of unit (including generator) and the square of the radius of gyration, ft.; H_0 = head acting on turbine before load change; L = length, ft., of enclosed water passages of turbine = sum of L_P (penstock) + L_c (casing) + L_d (draft tube); h = average (as distinguished from maximum) change in head, in ft., during time T, caused by inertia of water in passages; V = average velocity, ft. per sec., in enclosed water passages of turbine = $(L_P V_P + L_c V_c + L_d V_d)/L$; T = time, seconds, for gate movement; Hp._1 = load on turbine before gate movement; Hp._2 = load on turbine after gate movement; a = velocity of pressure wave in penstock, ft. per sec. In order to avoid danger of penstock collapse, T for load increases should be greater than $L_P V_P/12H_0$ and should also be greater than $2L_P/a$. (See page 2–59 for maximum pressure changes in penstocks.) With T in the above limits, h may be considered as LV/gT. Where the profile of the penstock departs appreciably from a straight line between intake and turbine, a greater value of T than otherwise is necessary, and a careful study should be made to avoid collapse.

Consider a sudden load increase, and neglect the time interval between the load change and the beginning of gate movement. The load demand in ft.-lb. during T is $\text{Hp.}_2 \times 550 \times T$. This is supplied partly by hydraulic energy acting on the turbine runner and partly by energy given up by WR^2 of the revolving element in slowing down from N to N_1.

The energy of the rotating mass $= MV^2/2 = WV^2/2g = \{W(2\pi RN/60)^2\}/2g = WR^2N^2/5870$. For a reduction of speed from N to N_1, the energy given up by the revolving mass is $\{WR^2(N^2 - N_1^2)\}$

It is not possible to determine exactly the amount of hydraulic energy supplied to the turbine during transition without analyzing the changes in quantity, head, efficiency, and gate opening, by subdividing T into smaller intervals. The method described by E. B. Strowger and S. L. Kerr in Speed Changes of Hydraulic Turbines for Sudden Changes of Load (*Trans.* A.S.M.E., xlviii, 1926), will give an accurate determination of this energy.

For practical purposes this hydraulic energy may be determined approximately as follows: With an absence of enclosed water passages we may consider that the average energy supplied during transition $= 1/2\,[550 \times T \times (\text{Hp.}_1 + \text{Hp.}_2)]$. If we consider the presence of enclosed passages, the effective head during transition $= (H_0 - h)$, and Q, average, is reduced in the ratio $\sqrt{(H_0 - h)/H_0}$; then the average energy supplied during transition $= 550 \times T \times 1/2\,(\text{Hp.}_1 + \text{Hp.}_2) \times \{(H_0 - h)/H_0\}^{3/2}$. Then we have

$$\text{Hp.}_2 \times 550 \times T = \frac{WR^2(N^2 - N_1^2)}{5870} + 550 \times T \times \left(\frac{\text{Hp.}_1 + \text{Hp.}_2}{2}\right)\left(\frac{H_0 - h}{H_0}\right)$$

or
$$N_1 = \sqrt{N^2 - \frac{\left[2\text{Hp.}_2 - (\text{Hp.}_1 + \text{Hp.}_2)\left(\frac{H_0 - h}{H_0}\right)^{3/2}\right] \times 1{,}620{,}000 \times T}{WR^2}} \quad . \quad . \quad [13]$$

Similarly
$$WR^2 = \frac{\left[2\text{Hp.}_2 - (\text{Hp.}_1 + \text{Hp.}_2)\left(\frac{H_0 - h}{H_0}\right)^{3/2}\right] \times 1{,}620{,}000 \times T}{N^2 - N_1^2} \quad . \quad . \quad . \quad [14]$$

Similarly, for sudden load decreases: The new load on the turbine is equal to the average hydraulic energy supplied during transition minus the energy absorbed by the rotating mass during increase in speed from N to N_1.

Or, transposing,

$$\frac{WR^2(N_1^2 - N^2)}{5870} = \frac{(\text{Hp.}_1 + \text{Hp.}_2)}{2}(550 \times T) \times \left(\frac{H_0 + h}{H_0}\right)^{3/2} - \text{Hp.}_2 \times 550 \times T$$

and
$$N_1 = \sqrt{N^2 + \frac{\left[(\text{Hp.}_1 + \text{Hp.}_2)\left(\frac{H_0 + h}{H_0}\right)^{3/2} - 2\text{Hp.}_2\right] \times 1{,}620{,}000 \times T}{WR^2}}, \quad . \quad [15]$$

or
$$WR^2 = \frac{\left[(\text{Hp.}_1 + \text{Hp.}_2)\left(\frac{H_0 + h}{H_0}\right)^{3/2} - 2\text{Hp.}_2\right] \times 1{,}620{,}000 \times T}{N_1^2 - N^2} \quad . \quad . \quad . \quad . \quad [16]$$

While the above formulas do not exactly take into account all factors, they have been found to be fairly close in actual practice. These formulas contain assumptions which are not correct, but apparently the latter compensate each other to a great extent. The regulation secured in practice is closer than computed by the above method, when the WR^2 of the various motors driven by the unit under consideration is not added to that of the generator. The speed change for increased loads is greater than for decreased loads. The reason is that in the former case, the increased hydraulic losses due to momentary operation at an inefficient relative speed, as well as the friction losses, aggravate or increase the speed change; whereas for decreased loads, these factors decrease the speed change and improve regulation. It will be noted, however, that consideration of the efficiency change and friction loss do not appear in the above formulas. It is generally the case that speed change for decreased loads is, in actual practice, of the greater importance, since loads usually are rejected more suddenly than they are taken on.

The time of gate movement T employed should never be less than about 1.25 seconds for complete travel, and should be slower than this with long penstocks in order that $LV/HT \leqq 12$, and also in order that $T > 2L/a$. If the latter requirements are fulfilled, T, in seconds, for governors should be, roughly, not less than

$$1.25 + (\text{Ft.-lb. of governor}/150{,}000).$$

The time of gate movement for part travel is less than for full travel, although the average rate is slower than for full travel. The following figures may be used as a guide:

Percent load change	100	75	50	25	10
Time of gate movement in percent of time required for full travel	100	87	72	57	48

It is usually allowable to have the speed change 12 to 14% for half the rated turbine capacity rejected, although some loads require closer regulation. A usual value of $WR^2\,N^2/\text{Hp.}$ is from 5,000,000 to 10,000,000. These values generally are exceeded where the value of H_0 is high.

INERTIA DUE TO PENSTOCK LENGTH.—The problem of satisfactorily allowing for the inertia due to excessive penstock length may be taken care of in three ways: 1. By providing a synchronous relief valve in conjunction with the turbine, which prevents velocity change in the penstock when the load on the turbine is changed. 2. By increasing the time of operation of the governor, in this way reducing the pressure change. 3. By the introduction of a surge tank as near the power-house as possible. This prevents sudden changes in velocity in that portion of the pipe line between the surge tank and the intake.

The provision of synchronous relief valves is employed frequently in the West, particularly where irrigation requirements necessitate a constant discharge from the turbine. At small load requirements there is, of course, a correspondingly large waste of water which is by-passed through the relief valve without doing effective work. This type of relief valve is connected directly to the operating ring of the turbine in such a way that a closing of the turbine gates results in a corresponding opposite movement of the relief valve, the sum of the discharge through the relief valve and the discharge through the turbine being a constant. Water-saving relief valves often are provided, which close at a slow rate after having been opened by the governor. While this type of relief valve prevents excessive pressure rises for sudden load decreases, it does not avoid the danger of penstock collapse for sudden load increases and for this condition, it is necessary that the time of governor operation be limited to such a value that LV/HT is not greater than about 12 and that $T>2L/a$. It is extremely important where a relief valve is employed, that its operation be positive. It is preferable that a rigid connection be provided between the valve and the operating ring, so that should the valve become stuck for any reason, the turbine gates also will be prevented from moving in the closing direction. Otherwise, should the relief valve become deranged, the turbine gates might close with disastrous results.

The second solution mentioned, *i.e.*, that of increasing the governor time, requires that means be provided to prevent the possibility of the governor ever operating at a faster rate than that decided upon. It often is not practicable to employ this method, since the flywheel effect resulting from the comparatively long time of gate operation is too great to be taken care of in the generator rotor, and the awkwardness of employing a separate flywheel frequently necessitates the final adoption of either the first or third methods mentioned.

Where practicable, the third solution, *i.e.*, the use of a surge tank, is the most to be desired. The adoption of a surge tank permits quick gate movements in both directions, without adding to the maintenance costs of the turbines by providing the additional

moving parts that are embodied in a relief valve, and without requiring any waste of water for sudden load rejections. The different types of surge tanks are discussed below.

SURGE TANKS.—Two types of surge tanks are in use: 1. The simple tank, consisting of a cylindrical tank with a pipe connection to the conduit; 2. The Johnson differential tank invented by R. B. Johnson. This tank differs from the simple tank primarily by the addition of a riser in the center of the tank proper. At the base of the riser, an annular port communicates with the tank, the port area being proportioned to suit the conditions under which the tank is to operate. See Fig. 26. With a simple tank, when the load is thrown on, the water level falls gradually to meet the increased demand prior to the acceleration of the water in the conduit between the tank and the intake. Since the water level in the tank falls comparatively slowly, there is only a correspondingly small head created to accelerate the water in the conduit to the new velocity required. With the differential tank, the water falls rapidly in the riser to meet the increased demand, establishing in a few seconds a relatively large accelerating head on the conduit. The level in the tank surrounding the riser falls slowly, supplying the demanded increment of water through the ports at the base of the riser. In the simple tank, the corrective action on the conduit velocity accumulates only as fast as the water level changes in the tank. Hence, the duration of the surge is much prolonged and the tank must be made larger. That is, for the same regulating ability, the differential tank can be made of smaller diameter and height than the simple tank.

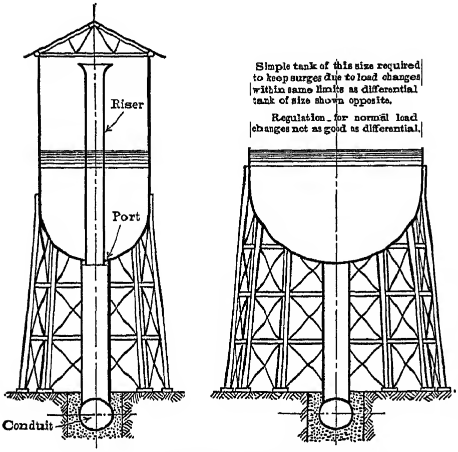

Fig. 26. Differential and Simple Types of Surge Tanks

Fig. 27 shows a comparison of the action of different types of surge tanks, as affecting the water level in the tank and the velocity in the conduit. The upper curves indicate the change of level in the tank and the lower group of curves, the conduit velocity. The time in seconds is reckoned from the instant at which the load is thrown on the turbine, followed practically immediately by the opening of the turbine gates. The curves for the restricted orifice type of tank refer to a form of differential tank, having, instead of a riser, restricted ports at the base of the tank. On account of the restricted openings this type gives relatively great pressure changes at the turbine, and is infrequently used on account of poor governing qualities.

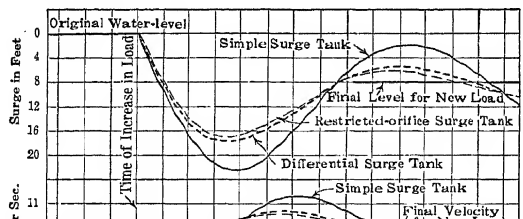

Fig. 27. Comparison of Action of Different Types of Surge Tanks

DESIGN OF SURGE TANKS.—The use of surge tanks to regulate conduit flow is involved and cannot be reproduced here. Reference is made to the following bibliography dealing with this subject: R. D. Johnson, Surge Tanks for Water Power Plants (*Tran-*

A.S.M.E., xxx, p. 443, 1908); by the same author, A Differential Surge Tank (*Trans.* A.S.C.E., lxxviii, 1915); D. W. Mead, Water Power Engineering, Chapter XIII, in which is set forth treatment of simple type of tank; Durand, Control of Surges in Water Conduits (*Trans.* A.S.M.E., xxxiv, 1912); Jakobuss, Surge Tanks (*Trans.* A.S.C.E., 1922). Fig. 27 is reproduced from Hydro-electric Handbook by Creager & Justin.

Maximum Pressure Changes in Penstocks Due to Gate Movements

Notation.—Let a = velocity of pressure wave along pipe, ft. per sec. (See Fig. 29); A = cross-sectional area of penstock, sq. ft.; g = acceleraton due to gravity, ft. per sec. = 32.2; h = pressure rise or excess head above normal, ft., also = pressure drop below normal, ft.; $h_{max.}$ = pressure rise due to instantaneous closure = aV_0/g, ft.; H_0 = initial steady head near turbine gates, corresponding to V_0, ft.; K = pipe line constant = $h_{max.}/2H_0 = aV_0/2gH_0$; L = length of penstock to forebay, or other point of relief, ft.; N = time constant or number of $2L/a$ intervals in time of closure = $aT/2L$; P = pressure rise as a proportion of $h_{max.} = h/h_{max.} = h \div (aV_0/g) = gh/aV_0$; Q_0 = initial steady flow in pipe prior to start of gate closure, corresponding to H_0, cu. ft. per sec.; T = time of gate movement for complete closure, if rate is uniform, sec. If rate is faster in middle portion of stroke than at beginning and end of stroke, as is usually the case, consider that $T = 0.85 \times$ time for complete closure; V_0 = velocity in pipe near turbine gates, corresponding to H_0 and Q_0, ft. per sec.; $Z = (2LV_0/gT\sqrt{H_0})^2$.

THE MAXIMUM PRESSURE RISE theory originally was developed by Joukovsky,* and expanded by Allievi,† Gibson,‡ and others. In his work, Allievi prepared a chart for determination of maximum total pressure. R. S. Quick§ devised the chart shown in Fig. 28 for determining the values of P. This chart may be used to obtain maximum pressure rise with uniform gate motion, and complete gate closure. For values of K and N falling to the left of the line marked Limiting Line for Maximum Pressure at End of First Interval, this chart may be used for partial gate closure.

Fig. 29 is a chart prepared by Quick to assist in determination of value of a for various penstocks. In this chart $a = 4660/\sqrt{1 + (Kd/Eb)} = 4660/\sqrt{1 + (d/100b)}$, where K = bulk modulus of elasticity of water, = 294,000; E = Young's modulus for pipe

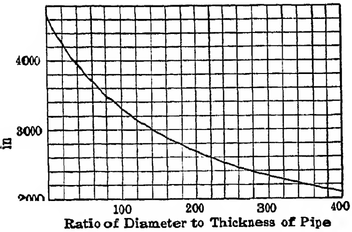

Fig. 29. Values of a

walls = 29,400,000 (approx.) for steel; d = inside diam. of pipe, in., b = thickness of pipe wall, in.

For values of N and K falling to the right of the almost vertical line in Fig. 28, it is important, as demonstrated by S. L. Kerr (New Aspects of Maximum Pressure Rise in Closed Conduits, *Trans.* A.S.M.E., v. 1, 1928), to reduce the rates of movement at the closing end of the gate stroke to prevent the pressure rise for partial gate movements to the closed gate position, from being greater than for complete gate stroke.

MAXIMUM PRESSURE DROP.—Methods for determining pressure drop are similar to those used for pressure rise. Fig. 30 is a chart developed by Kerr (Fall in Pressure in Hydraulic Turbine Penstocks due to Acceleration of Flow, Hydraulic Power Committee, 1924, N.E.L.A. publication No. 24–28) for obtaining value of fall in pressures h, for various values of Z. This chart is based on: Pressure rise h =

$$\tfrac{1}{2}\left(-Z + \sqrt{Z^2 + 4Z\ H_0}\right),$$

where

$$Z = \left\{\frac{2}{g} \times \frac{L}{T} \times \frac{V_0}{\sqrt{H_0}}\right\}^2$$

This formula will hold for any pipe line, where (1) rate of opening of gates is uniform, and (2) where T is not less than $2L/a$. T here is considered as the total time of gate movement. Where the gate movement is not uniform, the formula will hold for all practical purposes, but the maximum pressure drop in this case may occur near the end of the stroke instead of at the end of the first interval ($= 2L/a$).

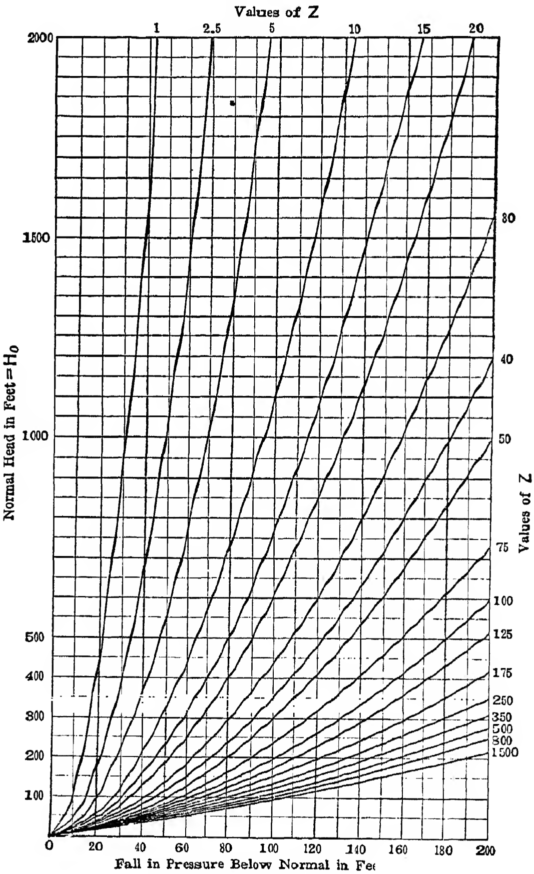

Fig. 30. Values of h

PENSTOCK VIBRATION.—Mechanical vibration in penstocks is discussed by J. P. Den Hartog in *Trans.* A.S.M.E., Hyd. 51–13, 1929. A mathematical analysis shows that objectionable vibrations occur in Francis turbines when the number of buckets on the turbine runner is one less than the number of guide vanes, and that satisfactory operation is obtainable when this relation is avoided. Results of tests showing agreement with the theory are given in the paper

7. IMPULSE TURBINES

The horizontal shaft type of impulse turbine, Fig. 2, is in more extensive use than the vertical type. A few vertical installations have been made with the usual design of bucket, and good efficiencies have been obtained by the provision of a suitable baffle to prevent loss of efficiency due to the discharge from the upper portion of the buckets. It is not considered practicable, unless efficiency is of small consideration, to adopt a value of N_s greater than about 8.0. The interval between this value (see Fig. 4) and the lowest allowable value of N_s with a reaction turbine is covered by the use of, preferably, multi-runner units, or multi-nozzle units or even multi-runner multi-nozzle units. Multi-nozzle units, that is, units with more than one nozzle per runner offer complications in design of operating mechanism and suffer loss of efficiency due to interference of the discharge from the two nozzles, unless very careful attention is given to the relative position of the nozzles. When the power to be developed with the head available results, with a single-runner single-nozzle unit in too low a value of r.p.m., a good arrangement may be adopted by locating a runner on each end of the generator shaft with the runners overhung. In addition to allowing, with a given value of N_s, a value of r.p.m. which is higher by $\sqrt{2}$ than that of a single-runner unit, this arrangement offers the advantage of allowing the shutting down of one runner at part load and the operation of the remaining runner at or about maximum efficiency. For large units it is the best practice, when the foregoing arrangement is adopted, to provide two separate governing mechanisms—one for each runner. A value of N_s = 3.8 generally is considered to be the highest value for which

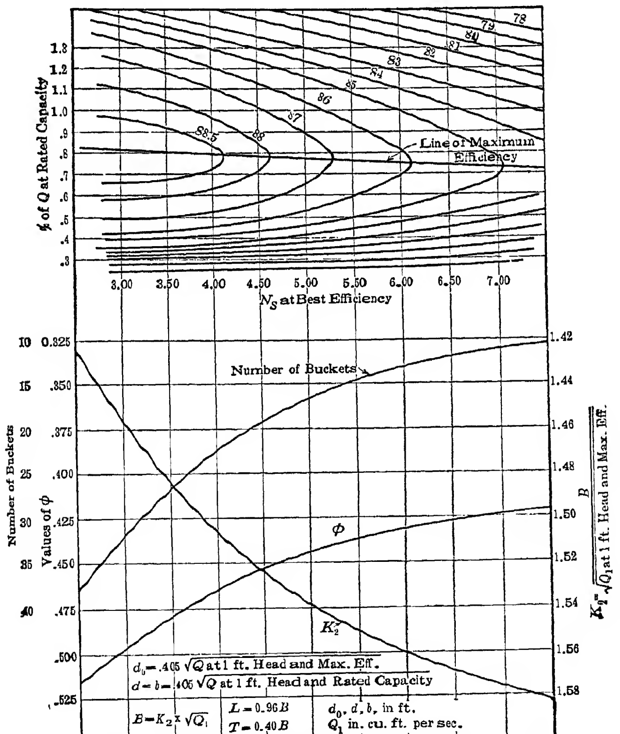

FIG. 31. Relation between ϕ and N_s

maximum possible efficiency may be attained. This value may be reduced indefinitely without appreciable reduction in efficiency. Fig. 31 gives an idea of the manner in which part-load efficiencies vary with N_s.

THEORY OF IMPULSE TURBINES.—The force exerted by a stream upon a bucket (Fig. 32) is $P = MC(1 - \cos\theta) = (W/g) \times C(1 - \cos\theta)$ . . . . . . [17] for a stationary bucket, where M = mass per sec. = W/g; C = velocity of stream, ft. per sec.; W = weight of water flowing per second, lb., and θ = angle through which water is turned relative to bucket, degrees. If the bucket is moving in the direction of the stream with a velocity U at the pitch diameter (see below), $P = (W/g)(C - U)(1 - \cos\theta)$. . [18]

Work done by stream $= PU = (WU/g)(C - U)(1 - \cos\theta)$. . . . . [19]

This is 0 when $U = 0$ and when $U = C$, and is a maximum when $U(C - U)$ is a maximum or when $U = {}^1/_2\,C$. When θ is greater than 90° the cosine becomes negative. For instance if $\theta = 174°$, $\cos = -\sin(174 - 90°) = -0.9945$. Then

$$PU = (WU/g) \times (C - U)(1 + 0.9945).$$

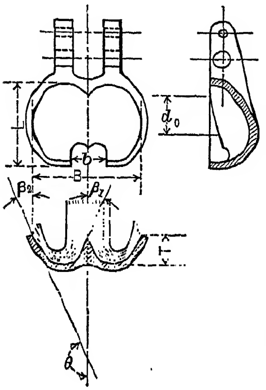

FIG. 32

Actually the water discharged must have some velocity and the value of U consequently is made somewhat less than ${}^1/_2\,C$, except at very low values of N_s. Fig. 31 indicates a relation between ϕ and N_s which has been established by test.* For derivation of ϕ, see page 2–45. The diameter of the circle which falls tangent with the center-line of the stream is known as the pitch diameter of the runner and it is at this point that ϕ is measured (Fig. 33). The value of ϕ at r (Fig. 33), it will be noted, decreases with increasing N_s. That, however, at r_a increases with increasing N_s due to increasing relative size of the buckets. The angle α at the center-line of the bucket should be calculated from the velocity triangle which obtains as the bucket enters the stream, where C = velocity of stream, u_a = that of bucket at radius r_a, and w_a = relative velocity. The under side of the bucket should be finished at a greater angle than α to avoid cavitation of the bucket. The number of buckets on a runner should be such that all portions of the stream will react on the bucket with the maximum attainable efficiency. Fig. 31 indicates the most efficient number and proportions of buckets as determined by the Reichel and Wagenbach tests.* By the relation of stream and bucket velocities it may be established that while the bucket travels from a to b, Fig. 33, the upper edge of the stream travels from a to c, and that the bucket cuts the stream along the line cb. Assume that when the bucket S is in the position shown, the next bucket is in the position T. In order for the particle of water at b to react upon the bucket T the latter must reach the position T' before b reaches the position b'. As a matter of fact the stream, particularly the under surface, reacts only very imperfectly on the bucket when the latter is in the position T'. Therefore the bucket T should be in some position T'', at the time b would reach b' if the bucket were removed. Good design dictates a value of ψ'' of from $0.6\,\psi'$ to $0.7\,\psi'$. On this basis $\psi''/(6.0 \times \text{r.p.m.})$ may be made equal to $(bb'/\sqrt{2gH_0})$. That is, bucket T will reach the position T'' in the time that a particle of water at b would reach b'. The angle between S and T represents the pitch, and for a fixed position for S, the position of T changes with the number of buckets selected. The tests of Reichel and Wagenbach demonstrated that it is important to maintain a small value of discharge angle β_2 (Fig. 32) even though the discharge comes into contact with the back of the bucket just ahead, causing appreciable stream deviation. Hence, backs of the buckets should be smoothly and carefully finished. Attention should be given to finishing the internal or working surfaces, and the intake and discharge angles β_1 and β_2.

BUCKETS.—The buckets are usually of bronze but may be of cast iron where the head is low, or of cast steel where the size of the buckets is relatively large. Accepted practice is to bolt them to the cast-steel hub with two or more fitted bolts, or to cast them integrally with the hub, when N_s is high. The latter should be of sufficient cross-section to resist the stresses at zero speed with maximum $P = (W/g) \times C(1 - \cos\theta)$, and at runaway speed with $P = 0$, also with centrifugal stresses, due to runaway speed of about 1.8 of normal speed. The dimensions B, L, T, of the bucket, it will be noted (Figs. 32 and 33) are considered in terms of $\sqrt{Q_1}$ at best efficiency, although the dimension b is dependent

* Tests of Turbine Buckets by Reichel and Wagenbach, *Zeit.* d. V.D.I., beginning March, 1913.

upon $\sqrt{Q_1}$ at rated capacity. Q_1 is the discharge Q reduced to 1 ft. head and is given by the formula $Q_1 = Q/\sqrt{H}$.

EXAMPLE.—Determine the outline dimensions of the buckets of an impulse wheel to develop 10,000 Hp. when operating at a head of 1000 ft., to generate 60-cycle alternating current.

Solution.—Assume N'_s at rated capacity to be 4.0. Then the speed will be

$$(N'_s \times H^{5/4}) \div \sqrt{\text{Hp.}} = (4.0 \times 1000^{5/4}) \div \sqrt{10{,}000} = 225 \text{ r.p.m.}$$

By adopting a two-runner unit, one-half of the horsepower will be developed in each runner, and the speed will be $(4.0 \times 1000^{5/4}) \div \sqrt{5000} = 318$ r.p.m. A generator at 300 r.p.m. will give 60-cycle current, and, the two-runner unit is selected. The value of N_s for this speed will be $N_s = (300 \times \sqrt{5000}) \div 1000^{5/4} = 3.772$.

The efficiency at rated capacity E_r may be assumed as 88.2%, whence the quantity of water at rated capacity

$Q_r = (\text{Hp.} \times 550) \div (W \times H \times E_r) = (5000 \times 550) \div (62.4 \times 1000 \times 0.882) = 50$ cu. ft. per sec.

In order to arrive at the value of N_s at best efficiency (Fig. 31) it is necessary to adopt the cut-and-try method. Assume as a trial, that Q at best efficiency $= Q_{m.e.} = 0.8 \times Q_r$, whence $Q_{m.e.} = 0.8 \times 50 = 40$ cu. ft. per sec. Assuming again a maximum efficiency E_m of 88.5%, Hp. at this efficiency will be,

$$\text{Hp.}_{m.e.} = (Q_{m.e.} \times W \times H \times E_m)/550 = (40 \times 62.4 \times 1000 \times 0.885)/550 = 4016.$$

The corresponding value of N_s at best efficiency = 3.3805. From Fig. 31, the maximum efficiency may be slightly greater than 88.5 for $N_s = 3.3805$, but it will be well to adhere to this value as the tests do not show higher values actually to have been reached. For $N_s = 3.3805$ at maximum efficiency, the efficiency at rated capacity is about 88.2% which corresponds with our original assumption. Also, it will be noted that the line of maximum efficiency crosses $N_s = 3.3805$ at about 0.8 of Q at the rated capacity, which checks our original assumption.

The best number of buckets (Fig. 31) corresponding to $N_s = 3.3805$ is 28. Also from Fig. 31, $\phi = 0.486$, whence

$$r = (\phi\sqrt{2gH} \times 60) \div (2\pi \times \text{r.p.m.}) = 0.486 \times \sqrt{64.4 \times 1000} \times 60) \div (6.2628 \times 300) = 3.93 \text{ ft}$$

Q_1 at max. effic. $= Q/\sqrt{H} = 40\ \sqrt{1000} = 1.265$ cu. ft. per sec.; Q_1 at rated capacity $= 1.265/0.8 = 1.58$.

Diameter of Jet: At maximum efficiency $d_0 = 0.405\sqrt{Q_1}$ at max. effic. = 0.455 ft. At rated capacity $d = 0.405\sqrt{Q_1}$ at rated capacity = 0.509 ft.

Dimensions of Buckets: From Fig. 31, $K_2 = 1.48$ for $N_s = 3.3805$.

Then B (Fig. 32) $= K_2 \times \sqrt{Q_1}$ at max. effic. $= 1.48 \times \sqrt{1.265} = 1.67$ ft.

$$L = 0.96B = 1.603 \text{ ft.}; \; T = 0.40B = 0.667 \text{ ft.}; \; b = d = 0.509 \text{ ft.}$$

NEEDLE NOZZLE.—The needle nozzle should be placed as close to the buckets as possible, as the stream tends to lose its compactness of form shortly after emerging from the nozzle, due partly to air friction, partly to the centrifugal effect caused by whirl components, and partly to expanding air in the water. The efficiency of a well-designed nozzle is usually between 95 and 97%, corresponding with a velocity in the free jet at its smallest point of between $0.975\sqrt{2gH}$ and $0.985\sqrt{2gH}$, where H = pressure head at d''' (Fig. 33) + the velocity head. Where d is the diameter of the free jet at the rated capac-

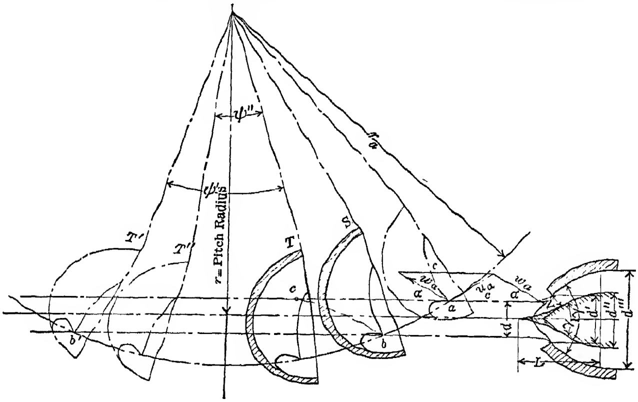

FIG. 33

ity of the unit, the main dimensions of the nozzle (see Fig. 33) may be found as follows:

$$d' = 1.25d;\ \gamma = 70 \text{ to } 80°;\ d'' = 1.55d;\ d''' = 3.2d;\ L = 2.2d.$$

The coefficient of contraction at exit from nozzle is about 0.75; that is, area of d divided by area $N = 0.75$. Care should be taken to have γ_1 smaller than γ (γ_1 being the angle of needle at the portion of greatest taper), otherwise this portion of the needle will be subject to corrosion due to the water not adhering to the needle surface. The needle as well as the nozzle near the outflow should be very smoothly finished. These parts should be made easily removable to provide for replacement when worn. Stainless steel for these parts gives excellent service against abrasion and pitting. It is most important that the flow be free from whirl components in approaching the nozzle. Often vanes, for straightening the flow at this point, are advisable.

The casing, in the vicinity of the nozzle, should be amply large to allow free discharge from the buckets. The remainder of the casing need only be large enough to clear the buckets, as windage is less than with needlessly large clearance. The discharge passage from the impulse wheel should have its outlet end above tail-water; otherwise the confined air in the casing will become entrained in the water, and the ejector action resulting will cause the water level in the discharge passage to rise until it reaches the runner buckets.

RELIEF VALVES.—The long penstocks usually necessary with impulse turbine installations prevent quick movement of the needle by the governor, particularly in the closing direction, unless there is a compensating opening of a relief valve to prevent injurious water hammer. Such relief valves are sometimes rigidly connected so that their movement is opposite to that of the needle, in which case there is no change in penstock velocity and hence no limitation on speed of needle movement. Such an arrangement of course offers the disadvantage that there is a waste of water when the unit is operating at small loads. More often the relief valve is connected to the needle through a dash-pot which allows the valve to close slowly after a quick closing of the needle with simultaneous opening of the valve. With such an arrangement there is danger of penstock collapse if the time of opening the needle be too short.

The governor capacity required is comparatively small, being only that necessary to overcome friction and the hydraulic load on the needle and relief valve or jet deflector; the latter can be balanced to a certain extent. The method of calculating regulation for sudden load changes (p. 2–55) applies to both impulse and reaction turbines.

JET DEFLECTORS often are used between nozzles and buckets. The governor moves these deflectors rapidly into the stream, thus cutting off the load rapidly without endangering the penstock. Following this movement the needle moves slowly to cut off the flow, and at the same time the deflector moves slowly out of the stream. The needle must move slowly in the opening direction for on-coming loads to avoid penstock collapse.

TURBINE COSTS cannot be given here, even approximately, as this item varies greatly with different makes of equipment, and also with labor and material costs which are always fluctuating more or less. Except possibly where the power to be developed is very small, it is advisable for the promoter or owner to have a reliable firm of consulting hydro-electric engineers examine, make surveys of, and submit a report on the advisability of proceeding with the development under consideration. Such a report involves a study of stream flow, head of water and power available, cost of the entire development, market available, probable revenue, and estimated rate of return on the investment.

In obtaining prices and data from turbine manufacturers the following information should be furnished: 1. Flow of water to be utilized, in cu. ft. per sec. 2. Normal head available, also maximum and minimum heads. 3. Maximum fluctuation of upper (head) and lower (tail) water levels. 4. Elevation of site of plant above sea level. 5. Number of units under consideration. 6. Importance of efficiency at part loads. 7. Length and diameter of penstocks, if any. 8. Frequency of electric current to be generated.

This information will enable the turbine manufacturer to make recommendations of type, unit capacity in Hp., and r.p.m. and to estimate the turbine and governor cost, as well as to prepare drawings of the equipment for the determination of power-house cost.

The importance of purchasing reliable and efficient equipment is very great where hydraulic turbines are concerned. This equipment is generally embedded in the substructure of the power house and can be replaced only at very great expense.

Manufacturers.—The principal manufacturers of hydraulic turbines are: Allis-Chalmers Mfg. Co., Milwaukee, Wis.; Baldwin-Southwark Corp., I. P. Morris Division, Philadelphia, Pa.; S. Morgan Smith Co., York, Pa.; The Pelton Water Wheel Co., San Francisco, Cal., a subsidiary of the Baldwin-Southwark Corp. The above firms manufacture reaction turbines of the Francis propeller and Kaplan types, impulse turbines, and governors. The Newport News Shipbuilding and Drydock Co., Newport News, Va., reaction turbines of the Francis and propeller types. James Leffel & Co., Springfield, Ohio, reaction and Kaplan type turbines. The Woodward Governor Co., Rockford, Ill., turbine governors.

PUMPS AND PUMPING ENGINES *

By Robert Thurston Kent

1. STEAM PUMPS

Notation.—B.Hp. = brake horsepower; I.Hp. = indicated horsepower of steam end of steam pump; W. Hp. = water horsepower; d = diam. of pump piston or plunger, in.; E_h = hydraulic efficiency, percent; E_m = mechanical efficiency, percent; E_v = volumetric efficiency, percent; G = U. S. gal. per min. = 7.4805 Q; H = head pumped against, ft.; H_l = total hydraulic losses (see below); h = suction head, ft.; l = stroke, in.; N = number of cycle strokes per min.; n = r.p.m. = number of cycles per min. (in duplex pumps n = 4 single strokes, counting both sides); p = total pressure, including suction lift, lb. per sq. in.; Q = displacement, cu. ft. per min.; Q_a = quantity of water actually pumped, cu. ft. per min.; v = piston speed, ft. per min.

CAPACITY, HORSEPOWER AND EFFICIENCY.—**Single Double-acting Pumps**: $v = lN/12$; $Q = \pi d^2 v/(4 \times 144)$; $G = 0.0408\, d^2 v$.

Duplex Double-acting Pumps: $v = ln/6$; $Q = 0.010908 d^2 v$; $G = 0.0816 d^2 v$. The displacement of piston rod must be deducted. If the piston rod is a single-acting plunger, its displacement will be 1/2 that given by above formulas.

Capacity, $Q_a = Q \times E_v$. For pumps in good condition, $E_v = 90\%$ approx.

Efficiency.—Mechanical efficiency is the ratio of work done in the water end to the work expended in driving the pump. For a steam pump, E_m = W.Hp./I.Hp.; for a power-driven pump, E_m = W.Hp./B.Hp. B.Hp. is taken as the power input at the pump coupling or pulley. Volumetric efficiency = $E_v = Q_a/Q$. Hydraulic efficiency = $E_h = (H + h)/H + H_l$.

Horsepower.—W.Hp. = $GwH/33{,}000 = Gp/1714$. At 60° F., W.Hp. = $GH/3960$. B.Hp. = W.Hp. $\times E_m$. See Table 1 for values of E_m.

Table 1.—Mechanical Efficiency of Various Types of Pumps
(Worthington Pump & Machinery Corp., Harrison, N. J.)

Type of Pump	Maximum Pressure, lb. per sq. in.	Stroke, in.										
		3	4	5	6	8	10	12	15	18	24	36

Thick liquid...	....	39	43	47	51	55	58	60	62	64	66	68

SLIP is the loss in displacement due to defective packing, leaky valves, etc. Slip = $(1 - E_v)$. Slip ranges from 3 to 5% in good pumps, and may be as low as 0.5% or even have a negative value in large pumps.

TOTAL HEAD ON PUMP is the pressure set up to lift the water in the suction pipe and force it through the delivery pipe to point of discharge. It includes the pressure required to overcome the resistance of valves and passages, and the friction losses in suction and delivery pipes.

Let H = total head on pump; H_s and H_d = total suction and delivery heads, respectively; h_f and H_f = friction losses in suction and delivery pipes; h_v and H_v = friction losses in suction and delivery valves; h_e and H_e = head lost at entrance to suction and delivery pipes; h_m and H_m = measured suction and delivery heads; h_p = velocity head in suction pipe; H_p = final velocity head; h_g and H_g = distance from center of pump to center of suction and discharge gages, ft., all measured in ft. of head; v and V = velocity in suction and discharge pipes, ft. per sec.; p_s and p_d = pressure on suction and discharge gages, lb. per sq. in. ($p_s <$ atmospheric pressure); $g = 32.2$; W = weight of water, lb. per cu. ft. Then $H_s = (h_e + h_f + h_v + h_p + h_m)$; $H_d = (H_e + H_v + H_f + H_p + H_m$; $h_p = (v^2/2g)$, and $H_p = (V^2/2g)$. $H = (h_s - h_p + H_d)$ when suction and delivery pipes are the same size. $H = [\{(144 p_s/W) \pm h_g\} - (v^2/2g)] + \{(144 p_d/W) + (V^2/2g)\}$. If

* The author acknowledges the assistance of Mr. Paul Diserens, Consulting Engineer of the Worthington Pump & Machinery Corporation in the revision of this section.

suction pipe gage is above center line of pump, h_g is plus; if below h_g is minus. The friction losses, h_v, H_v, and H_e usually are included in the efficiency factor of the pump; then $H = h_e + h_f + h_m + H_m$.

Loss of head at entrance of suction pipe, $h_e = (mv^2/2g)$; values of m may be taken as: 0.49 for orifice flush with wall; 0.93 for orifice projecting inwardly beyond wall; 0 for pipe with mouthpiece. (See also p. 2–12.) The same formula applies to the delivery pipe, V being substituted for v.

Values of h_f and H_f depend on the roughness of the interior pipe surface and the resistance due to bends, valves, etc. According to Merriman (Treatise on Hydraulics), $h_f = f\,(l/d) \times (v^2/2g)$, where l = length of pipe, ft.; d = diameter, ft.; f = coefficient of roughness of surface, ranging from 0.1 to 0.5 for new clean iron pipe; f increases with increase of d, and decreases with increase of v. (See also pp. 2–14—2–21.)

Loss of head due to bends, $h_b = Kf(l/d) \times (v^2/2g)$, where K = a factor depending on the ratio R/d, where R = radius of bend and d = diam. of pipe; l = length of center line of bend, ft. Values of K are:

R/d =	5	10	15	20	25	30
K =	2.04	1.67	1.52	1.45	1.425	1.42

Loss of head due to valves, cocks, etc., $h_q = (mv^2/2g)$, where m = factor depending on closure of valve. Greene (Pumping Machinery) gives values of m as follows:

d_1/d	= 0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.86
Gate valves, m	= 0.1	0.5	1.1	2.1	3.2	8.6	20.2	60.0	140
θ	= 10	20	30	40	50	60	61	65	
Cocks, m	= 0.1	1	4	12	34	120	....	280	
Butterfly valves, m	= 1	2	7	18	55	206	280	....	

d = diam. of pipe, in.; d_1 = distance from top of pipe to lowest point of gate disc; θ = angle between axis of pipe and axis of valve, deg. F. W. Isles (*Mech. Engg.*, July, 1932) reports that experiments with various forms of cocks showed that one in which the plug was cored to the form B in Fig. 1 had a frictional resistance to flow of about one-half that of the regular form of plug A, Fig. 1, and that for a given pressure loss would discharge about 35% more fluid than the regular cock.

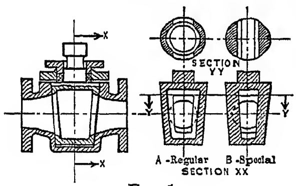

FIG. 1

Loss of head due to sudden enlargement in suction or delivery pipe,

$$h_{en} = (v_s - v)^2/2g = \{1 \cdot$$

where v_s and v = respectively, velocity before and after enlargement; A_s and A = area before and after enlargement.

Loss of head due to sudden contraction in suction or delivery pipe,

$$h_c = \{(1/K) - 1\}^2 \times (v_s^2/2g);\ K = 0.582 + \{0.0418/(1.1 - \rho)\}$$

where ρ = ratio of diameters of small and large pipes. See Greene's Pumping Machinery, 2d ed., chap. v, for a mathematical discussion of the various losses in a pump.

DUTY OF A PUMP is the number of ft.-lb. of energy delivered by the pump for every 1000 lb. of dry steam or every 1,000,000 B.t.u. supplied to it. See Table 2 for probable duty of various types of pumps and pumping engines.

The rate of feedwater consumption is the figure given in Table 2 divided into 1980, thus: if the duty of a pump is 88 million ft.-lb. per 1000 lb. of dry steam, the rate is: 1,980,000,000/88,000,000 = 22.5 lb. per Hp. per hr.

DEPTH OF SUCTION.—The theoretical maximum depth from which a pump will draw water, H_s, is the head corresponding to a perfect vacuum = 14.7 lb. × 2.309 = 33.95 ft. Actually H_s is not over 26 ft. under most favorable conditions, due to valve leakage, entrained air, and the vapor of water itself. In a new installation handling cold water, $H_s \gtreqless 22$ ft., being less as the temperature of the water increases. H_s also decreases as altitude above sea level increases. See Table 3 for effect of increase of temperature and altitude. Hot water should flow to the pump by gravity.

VELOCITY OF WATER IN SUCTION AND DELIVERY PIPES.—Increase of velocity of water increases the friction head. Pump manufacturers recommend the following as *maximum* velocities: In *suction pipe*, 240 ft. per min.; in *delivery pipe*, 300 ft. per min. If d = diam. of pipe, in.; G = gal. of water per min.; V = velocity, ft. per min.; $d = 4.95\sqrt{G/V}$. Suction and discharge lines should be at least of the diameter indicated by the flanges on the pump; for long runs, particularly of the suction line, they should be larger. Air pockets should be avoided. See Fig. 2. The submergence of the suction pipe should be at least $4d$ for large pipes, and $3d$ for small ones.

PISTON SPEEDS of direct-acting steam pumps for various classes of service are given in Tables 4 and 5.

SIZE OF STEAM CYLINDER, DIRECT-ACTING PUMPS.—Let A = area of steam piston, sq in.; F = force of thrust on steam piston, lb. = $A \times$ M.E.P.; W = load on water plunger, lb. = $a \times w = F \times E_m$; a = area of water plunger, sq. in.; W = pressure on or resistance of water plunger, lb. per sq. in.; M.E.P. = mean effective pressure in steam cylinder, lb. per sq. in.; E_m = mechanical efficiency (See p. 2–65 and Table 1. In calculating proportions of steam cylinders, values of E_m equivalent to 90% of those given in Table 1 are recommended); P = absolute pressure in high-pressure cylinder = boiler pressure + 10, lb. per sq. in.; b = back pressure (absolute), lb. per sq. in.; maximum values of b are: non-condensing steam ends, b = 16; compound condensing steam ends, b = 6; triple-expansion condensing steam ends, b = 5; A_h, A_i, A_l = area of high, intermediate and low pressure cylinders respectively; R = ratio of cylinder areas = $\sqrt{P/b}$ = 4 (max.) for compound steam ends; for triple-expansion steam ends, $R_1 = A_l/A_h = \sqrt[3]{(P/b)^2} = 8$ (max.); $R_2 = A_i/A_h = \sqrt{R_1} = 3$ (max.).

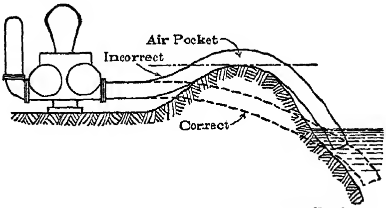

Fig. 2. Correct and Incorrect Installation of Suction Line

Then M.E.P. = $P - b$ (simple); = $\{2P - (P/R) - bR\}$ (compound, referred to h.p. cyl.); = $\{3P - 2(P/\sqrt{R_1}) - bR_1\}$ (triple expansion, referred to h.p. cyl.).

Values determined by the above formulas are not absolute. Actual mechanical effi-

ciencies may exceed those in Table 1, when a pump is in first class condition. The steam end of a direct-acting pump, however, must be designed to take care of unfavorable conditions, since power cannot be increased by later cut-off.

SIZE AND NUMBER OF VALVES.—For the theory underlying the determination of size and number of valves, and also loss of head in the passage of the water through them, see Greene's Pumping Machinery, 2d ed., chap. v.

Let A_p = area of plunger, sq. in.; S = piston speed, ft. per min.; A = gross area of valves, sq. in.; a = free valve area, sq. in., in each corner of pump; n = number of corners = 4 in single pumps and 8 in duplex pumps; N = number of valves; d = diam. of valve seat, in.; L = lift of valve, in. Then $a = \pi dL = 0.5\ A_pS$ to $0.6\ A_pS$; $A = na$, $N = A/0.7854d^2$. These formulas are based on a water velocity of 167 to 200 ft. per min. Thick viscous liquids require greater valve area, which may be as high as 75 to 100% of the plunger area, depending on the viscosity of the liquid.

Figs. 3 to 8 show various forms of pump valves. In rubber disc valves for pressures up to 75 lb. per sq. in., the rubber may be soft; up to 150 lb., medium hard; above 150 lb., hard, of special composition. The disc type metal valve is of bronze with ground joint on the seat. These valves are for general service and thin liquids. The ball valve is used with thick, viscous liquids, as tar, paper pulp, etc. The angle of the seat to center line of valve should not exceed 45°, and lift may be $0.1d$ to $0.25d$. The wing guided valve is used for pressure pumps, and may have a flat or conical ground seat, or be faced with rubber.

Barr, in Pumping Machinery, gives the dimensions of valve discs as follows:

Diam. of disc, in.	2	2 1/2	3	3 1/2	4	4 1/2	5
Thickness, in.	3/8	7/16	1/2	5/8	5/8	3/4	3/4
Diam. of hole	1/2	1/2	9/16	5/8	11/16	13/16	13/16
Size of spring wire, B.W.G.	12	12	10	10	8	8	8

The thread on the valve seat to fit the valve deck should taper 1 in. per ft. Diam. of valve stems = (diam. of hole − 1/16 in.). The plate on top of the valve disc should be 3/4 diam. of disc and 1/32 in. thick; 1/16 in. thick for valves 4 1/2 in. and over. Diameter of coil of springs usually is 1/2 the valve diameter, and 5 turns give sufficient elasticity.

Wing Guided Valves

Types of Valves

AIR CHAMBERS to compensate for irregularities in flow of water should be placed on both delivery and suction lines. Fig. 9 shows approved methods of installation on suction lines. Let V = volume of air in chamber when pump is operating, cu. ft.; V_1 = minimum volume of chamber that will avoid losing water with pump idle; h and h_1 = respectively, head on pump when operating and idle, ft. = maximum permissible variation in pressure in air chamber; D = a factor explained below. Then $V = D/p$ and $V_1 = Vh/h_1$. Value of D may be determined graphically.

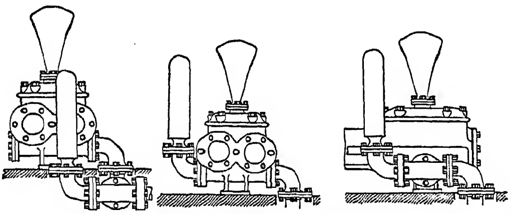

FIG. 9. Methods of Installing Air Chambers

EXAMPLE.—In Fig. 10, the curves PP represent the discharge of the two sides of a duplex double-acting pump, the dotted curves the resultant discharge, and the line AB the mean discharge. Areas e_1, e_2, e_3 represent quantities of water delivered to the air chamber, and areas d_1, d_2, d_3, quantities delivered by the air chamber. Then D = greatest difference between the largest values of e and d respectively. An empirical rule (Greene) is $V = 3C$ to $6C$ for single-acting pumps; $V = 1.5C$ to $4C$ for double-acting pumps, where C = cylinder volume. The volume of the vacuum chamber on the suction line should equal that of the air chamber.

BOILER FEED PUMPS.—In determining the proper size of pump for a steam boiler, allowance must be made for sufficient water to cover all the demands of engines, turbines, steam heating, etc., up to the capacity of the boiler. In practice, engines use from 12 to 50 or more pounds of steam per Hp.-hr., when being worked to capacity. When an engine is overloaded more water per horsepower will be required than when operating at its rated capacity.

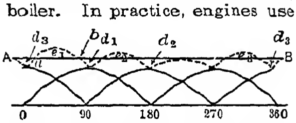

FIG. 10. Determination of Air Chamber Volume

The pump should not be chosen on the basis of Boiler-Hp. It is best to calculate the amount of steam used in the plant and select the size of feed pump that will handle this amount at a moderate speed.

PUMP FITTINGS.—The liquid pumped determines the kind of material used in the pump. The following are the designations of the types of pump fittings in general use. *Plain-fitted Displacement Pumps.*—Bronze-lined pump cylinders, iron pump pistons, steel rods, bronze or rubber valves, bronze valve seats, guards and springs. *Plain-fitted Centrifugal Pumps.*—Iron impellers, steel shafts, bronze impeller bushing rings. *Bronze-fitted Displacement Pumps.*—Bronze lined pump cylinders, bronze piston rods, valve seats, guards and spring, bronze or rubber valves, iron pump pistons. *Bronze-fitted Centrifugal Pumps.*—Bronze impellers, impeller bushing rings, bronze or bronze-covered steel shaft. *Full Bronze-fitted Displacement Pumps.*—Bronze-lined pump cylinders; bronze

pump pistons, piston rods, valve seats, guards, and springs; bronze or rubber valves. *All Iron.*—All parts in contact with liquid of cast or malleable iron. Steel piston rods or shafts. *All Bronze.*—All parts in contact with liquid of bronze. Bronze, or bronze-covered piston rods and shafts. *Cast-iron lined.*—Liquid cylinder of cast-iron, lined with lead or wood.

The Worthington Pump & Machinery Corp. gives the following types of fittings as best adapted to the liquids named:

All Bronze.—Acids: Acetic, Carbolic, Fatty, Hydrochloric, Mine Water, Nitric, Sulphuric (dilute). Alcohol. Beer and Beer Wort. Bitter-water. Brine (over 3% salt). Calcium-acid-sulphate (conc.). Calcium-chlorate. Copper-sulphate. Ferric Hydroxide. Glycerine. Grape Juice. Magnesium-acid-sulphate, magnesium-oxy-chloride. Milk. Nickel-chloride, nickel-sulphate. Hydrogen peroxide. Potassium-chloride, potassium-nitrate, potassium-sulphate. Sodium-chloride. Strontium-nitrate. Sugar. Sulphur-dioxide. Syrup. Tan Liquor. Vinegar. Vitriol (blue). Yeast. Zinc-nitrate, zinc-sulphate.

All Iron.—Acids: Carbolic, cyanic, hydrocyanic, nitric, sulphuric (conc., fuming and 60° B). Alkaline liquid. Ammonia. Ammonium-chloride, ammonium-nitrate, ammonium-sulphate. Aniline water. Asphaltum. Benzine (coal tar product). Bichloride of mercury. Carbonate of soda. Caustic-lye, caustic-manganese, caustic-soda. Chloride of zinc. Cyanide of sodium, cyanide of potassium. Ferrous chloride. Lard. Lime Water. Lye. Magnesium-sulphate. Milk of lime. Oils: Light lubricating, creosote, cocoanut, gas, rape, turpentine, wash. Potash. Potassium-alum, potassium-carbonate, potassium-cyanide. Salammoniac. Soap. Sodium-bicarbonate, sodium-carbonate, sodium-hyposulphite, sodium-sulphate, sodium-sulphide (hot). Tar. Vitriol (green).

Plain Fitted.—Acids: Carbolic in H_2O, citric. Alum. Ammonium bicarbonate. Barium-chloride, barium-nitrate. Carbon tetrachloride. Cellulose. Glucose. Hydrogen-sulphide. Marsh gas. Sodium sulphide. Oils: Cottonseed, fuel, kerosene.

Bronze Fitted.—Oils: Crude, fuel, linseed. Water, fresh.

Full Bronze Fitted.—Beet juice. Benzine (Petroleum ether). Brine. Calcium chloride, salt (3%). Calcium-acid-sulphate. Creosote. Dyewood Liquor. Gasoline. Glue. Heptane. Magnesium-acid-sulphate. Mash. Molasses. Naphtha. Paraffine (hot). Sea water. Sewage. Slop, brewery. Starch. Varnish. Water, -distilled, -sulphur. Wood Pulp. Zinc-chloride, zinc caustic.

2. PUMPING ENGINES

THE WORTHINGTON HIGH-DUTY PUMPING ENGINE substitutes for a flywheel a pair of oscillating hydraulic cylinders, which receive part of the energy exerted by the steam during the first half of the stroke, and give it out in the latter half. For description see catalog of Worthington Pump & Machinery Corporation, Harrison, N. J. A test of a triple-expansion condensing engine of this type is reported in *Eng. News*, Nov. 29, 1904. Steam cylinders 13, 21, 34 in.; plungers 30 in.; stroke 25 in. Steam pressure, 124 lb. Total head, 79 ft.; capacity, 14,267,000 gal. in 24 hr. Duty per million B.t.u., 102,224,000 ft.-lb.

THE d'AURIA PUMPING ENGINE substitutes for a flywheel a compensating cylinder in line with the plunger, with a piston which pushes water to and fro through a pipe connecting the ends of the cylinder. It is built by the Builders' Iron Foundry, Providence, R. I.

A 72,000,000-GALLON PUMPING ENGINE at the Calf Pasture Station of the Boston Main Drainage Works is described in *Eng. News*, July 6, 1905. It has three cylinders, 18 1/2, 33 and 52 3/4 in., and two plungers, 60 in. diam.; stroke of all, 10 ft. The piston-rods of the two smaller cylinders connect to one end of a walking beam and the rod of the third cylinder to the other. Steam pressure 185 lb. gage; revolutions per min. 17; static head 37 to 43 ft. Suction valves 128; ports, 4 × 16 1/4 in.; total port area 8576 sq. in. Delivery valves, 96; ports, 4 × 16 3/4 to 20 3/4 in.; total port area 7215 sq. in. Valves are rectangular rubber flaps, backed and faced with bronze and weighted with lead. They are set with their longest dimension horizontal, on ports inclined about 45° to the horizontal. At 17 r.p.m. the displacement is 72,000,000 gal. in 24 hr.

THE SCREW PUMPING ENGINE of the Kinnickinick Flushing Tunnel, Milwaukee, has a capacity of 30,000 cu. ft. per min. (= 323,000,000 gal. in 24 hr.) at 55 r.p.m. The head is 3 1/2 ft. The wheel 12.5 ft. diam., made of six blades, revolves in a casing set in the tunnel lining. A cone, 6 ft. diam. at the base, placed concentric with the wheel on the approach side diverts the water to the blades. A casing beyond the wheel contains stationary deflector blades which reduce the swirling motion of the water (Allis-Chalmers Co., Bulletin No. 1610). The two screw pumping engines of the Chicago

sewerage system have wheels 14 3/4 ft. diam., consisting of a hexagonal hub surmounted by six blades, and revolving in cylindrical casings 16 ft. long, allowing 1/4 in. clearance at the sides. The pumps are driven by vertical triple-expansion engines with cylinders 22, 38 and 62 in. diam., and 42 in. stroke.

NOTE 1.—The above were all vertical triple-expansion crank-and-flywheel pumping engines, each with three single-acting plungers. Nos. 1 and 3 were Worthington-Holly engines, Nos. 2, 4, and 5 were Allis-Chalmers engines. The data are taken from official reports. Nos. 2 and 3 had been installed about 20 years and are good examples of economy after a long period of operation. Nos. 1, 4 and 5 were new when tested. No. 4 thermal efficiency of 24.27% included a feedwater heater attached to the second receiver; its thermal efficiency without this heater was 21.61%. Nos. 1, 2, and 3 had no second receiver-heaters.

NOTE 2.—The above are crank-and-flywheel engines each with two double-acting plungers and were new when tested. The data are taken from official reports. Nos. 1 and 4 are Allis-Chalmers engines. Nos. 2 and 3 are Worthington-Snow engines.

DUTY TRIALS OF PUMPING ENGINES. For method of conducting tests of pumping engines, see p. 16-36.

3. POWER PUMPS

A power pump is driven by a source of power not integral with the pump, as a motor, turbine, steam or oil engine, water wheel, line-shaft, etc. The standard types generally used have a common crankshaft to which the pumps are connected. A duplex pump usually has two double-acting pumps with cranks set 90° apart. A triplex pump has three single- or double-acting pumps with cranks set 120° apart.

The advantages of these pumps over single pumps is a more even flow, which means more frequent but much less severe pulsations in the discharge, with consequently lower

stresses in discharge piping due to water hammer. Sizes and capacities of power pumps are given in Tables 8 and 9.

4. ROTARY PUMPS

A rotary pump is a positive displacement pump driven from an independent prime mover through a rotating shaft. The most commercially successful types are: 1. The gear pump. A pair of gears rotate in a casing. They entrain liquid between the teeth

ADVANTAGES OF ROTARY ... ed to reciprocating pumps the rotary pump is more compact and ... It has no valves or mechanism for converting rotary into reciproc ... occupies less space and requires less attention. Compared wi ... rotary pump delivers practically constant volume at a given ... of change in head. It will pick up its suction. It can ... ities and high heads, and can be run at low speed ... thick viscous liquid.

LIMITATIONS OF ROTARY PUMPS.—The greatest limitation is lack of means of compensating for wear. Close-fitting surfaces in metallic contact, or with slight clearance, are required. Wear or damage of these surfaces lowers capacity and efficiency of the pump. There being no adjustments or packings, normal condition can be restored only by installation of new parts. Foreign substances in the liquid are most injurious. Corrosion of finished surfaces produces an oxide that causes rapid wear. Since lubrication from outside would contaminate the liquid, running parts depend for their lubrication on the liquid being pumped. The rotary pump is best adapted to pump oils or other liquid with considerable lubricating value, although it often is used for water and liquids of low lubricating value. It is well adapted to load and discharge bulk cargo mineral or vegetable oils, to pump petroleum products in refineries, and lubricating oil for machinery.

CAPACITY AND PRESSURE of rotary pumps range from a fraction of a gallon per min. to 5000 gal. per min. In general, pressures are low, and many manufacturers limit their product to 100 or 200 lb. per sq. in. Some builders offer special construction for pressures up to 5000 lb. per sq. in.

EFFICIENCY of the better class of rotary pumps is good. In small-capacity pumps, efficiencies run considerably higher than those of centrifugal pumps. In large-capacity pumps at higher pressures, the efficiency may range from 85 to 90%. The speed of rotation and viscosity of liquid being pumped materially affect efficiency.

5. DEEP WELL PUMPS

Deep well turbine pumps in recent years have largely displaced the reciprocating type of deep well pump although the latter still is (1935) used. Present capacities of deep well turbine pumps range from 20-gal. per min., from 4- or 6-in. wells, to several thousand gallons per min. in 24-in. wells. Table 10 gives approximate capacities of both reciprocating and turbine pumps.

Turbine pumps have standardized impeller units, and are almost invariably multistage. The number of stages depends on the total head against which the pump operates. The drive usually is a direct-connected vertical motor. Usual speeds are 1750, 1450, or 1150 r.p.m., depending on size and current characteristics, except that with 4- and 6-in. pumps, 3500 r.p.m. is common. The motor is generally a vertical, hollow-shaft type with a ball or roller bearing in the upper bracket large enough to carry both

Table 10.—Approximate Capacities of Deep-well Pumps

the weight of the rotor and the pump thrust load. Other drives used are: Vertical, solid shaft motor with flexible coupling; vertical steam turbine; right-angle gear; multi-V-belt.

Impeller units usually are assembled in a group at the lower end of the pump and always are submerged, with at least 10 ft. of suction pipe and a strainer below them. The column pipe to conduct the water to the surface, and the line shafting to transmit power to the impeller shaft, connect the impeller units with the discharge fitting at ground level. Line shafting usually is enclosed in a cover pipe with bronze bearing at suitable intervals to avoid critical running speed. With such construction, bearings are lubricated by oil introduced at the top of the cover pipe. With an open line shaft and non-metallic (usually rubber) bearings, lubrication is by the water being pumped. Fig. 11 shows a typical Worthington deep well pump driven by a hollow shaft motor.

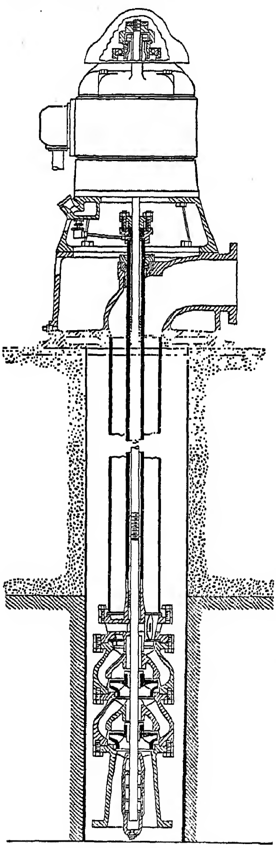

Fig. 11. Deep Well Turbine Pump

6. PUMPING BY COMPRESSED AIR

THE AIR-LIFT PUMP comprises a vertical water, or eduction, pipe, whose lower end is submerged in a well, and a smaller pipe delivering air into it at the bottom through a foot-piece. The rising column in the eduction pipe is a mixture of air and water, which is lighter than a column of water of equal height. Hence, the column in the pipe is raised above the level of the surrounding water. The *standing level* is the level of the water before pumping begins. The *pumping level* is the level to which the water recedes after pumping begins. The *lift* is the height of point of discharge above pumping level. *Submergence* is height from point of air injection to pumping level. If H = lift, ft., and S = submergence, ft., Submergence Ratio $= S/(S + H)$.

The upward velocity of each air-bubble in the rising air-water mixture in the eduction pipe is due to a force equal to the difference in weight of the bubble and of the water it displaces. The water may be raised a certain distance without flowing from the eduction pipe, the air escaping at the same rate that it is admitted. All its energy is dissipated in slippage without performing useful work. Slippage may be decreased by reducing the size of the bubbles and by increasing velocity of mixture in the eduction pipe. Other energy losses are: 1. Friction of mixture in eduction pipe. 2. Friction losses in the water prior to admitting air. 3. Kinetic losses in water due to velocity of discharge.

FRICTION LOSSES.—Gibson (Hydraulics, p. 703) gives a formula of the form $h_f = \{f(H + S)v^2\}/2gm$, where h_f = head lost in friction, ft. of column of mixture; f = coefficient of friction, H = lift, ft.; S = submergence, ft.; v^2 = mean square of the velocity in the pipe, ft. per sec.; m = mean hydraulic depth; g = 32.2. Gibson gives values of $f = 0.033$ in 3-in. pipes, with = 12.16, to $f = 0.023$ in a 12-in. pipe with $v = 6.5$. The value of f for a mixture of air and water is about 6 times that of f for water alone. Owens gives f = 0.025 in a 6 5/8-in. pipe with a mean value of $v = 13.3$.

Kinetic Losses may be reduced by a conical or expanding mouthpiece on the discharge outlet.

THEORY OF THE AIR-LIFT PUMP has been approached from three standpoints. They are discussed by A. W. Purchas (*Proc.* Inst. M.E., Nov., 1917) as follows: 1. Loren's theory which has been shown to contain so many errors as to be totally unreliable. 2. A theory which assumes the motive power operating the pump to be the difference in specific gravity between the water outside the eduction pipe and the mixture of air and water within it. 3. The Displacement Theory, which assumes each bubble of air to displace an equal volume of water in the eduction pipe, and therefore raises the water level therein a distance $h = V/A$, where V = volume of bubble and A = area of pipe.

Let H = lift, ft.; S = submergence, ft.; V_a = volume of air, cu. ft. per gal. of water, required at absolute atmospheric pressure; P_a = lb. per sq. ft., to raise a volume V_w, cu. ft. of water; P_s = absolute pressure of air leaving foot-piece, lb. per sq. ft.; h_f = friction loss in eduction pipe; h_s = head lost in slip in eduction pipe; h_k = head equivalent to velocity with which water leaves the outlet. Then for the theory based on the difference in specific gravity (2) Purchas gives:

$$\frac{V_a}{V_w} = \frac{H + h_f + h_s + h_k}{\div (P_s - P_a)}$$

Ivens (Pumping by Compressed Air) gives the following modification of this formula: $V_a = H \div C \log \{(S + 34)/34\}$, in which values of C are as follows:

H = 10–60	61–200	201–500	501–650	651–750
C = 245	233	216	185	156

Discussing the displacement theory, Purchas assumes that the injection of a bubble of air of volume V, causing a rise h in the height of water in the eduction pipe, does work equal to $^1/_2\ Vh$. The bubble expands isothermally as it rises, increasing h, but losing none of its energy until it escapes at the surface. This theory assumes that no energy is lost in slip until the bubble escapes. When a sufficient volume of air V_x has accumulated in the eduction pipe, so that $h = (V_x/A) > H$, the pump will discharge a volume of liquid equal to $A(h - H)$, and the further operation may be regarded as a head $(h - H)$ forcing liquid into that area of the eduction pipe not already filled with air.

The energy supplied by the air to the water is $P_a V_a \log_e (P_s/P_a)$ ft.-lb., and the work done on the water is 62.5 $V_w H$ ft.-lb., V_a and V_w being in cu. ft. per min. Therefore, if E is efficiency of the pump,

$$\{P_a V_a \log_e (P_s/P_a)\} E = 62.5 V_w H.$$

For values of P_s, see Submergence, below.

The volume of air V_p passing any point x in the eduction pipe per unit of time, is given by

$$V_p = V_1(P_a/P_s) + V_1(x/H)\{1 - (P_a/P_s)\},$$

where V_1 = volume of air delivered to pump, cu. ft. per sec., measured at pressure P_a and temperature of liquid being pumped, x = distance, ft., of the point under consideration above the point of air injection. Volume of air and area of pipe being known, average velocity may be determined.

SUBMERGENCE.—The most suitable value is found by experiment; it usually lies between 65% and 75%. The relation of submergence to lift has an important bearing on efficiency (Owens). A. W. Purchas (*Proc.* Inst. M. E., Nov., 1917, p. 613) gives the following values as a fair average of current practice.

Lift, ft	25	50	75	100	150	200	250	300
Ratio, Submersion/Lift...	4.0	3.0	2.33	2.00	1.70	1.38	1.22	1.00
Submersion, ft...........	100	150	175	200	255	275	305	300

Submergence Ratio.—The most suitable value is found by experiment, and after the piping is in place it is altered to suit. Submergence ratio ranges from 30 to 70%. It has an important effect on the cubic feet of air required, and thus reflects on the efficiency. Average values are given on p. 2–77.

AIR PRESSURE REQUIRED.—Based on the values of submergence ratio given above, Purchas gives for air pressure required, $P_s = P_a + 0.434S$, where P_s = absolute pressure of air, lb. per sq. in., under the submergence head S, P_a = absolute pressure of atmosphere, lb. per sq. in., S = submergence, ft. The starting pressure is higher than operating pressure. It is equivalent to the height of water level (at rest) above the end of the air pipe.

VELOCITY OF RISE OF BUBBLES.—Experiments by Owens (*Engg.*, Sept. 23, 1921) show that the velocity of rise of bubbles depends on their diameter. The following values were determined in water at 76° F.:

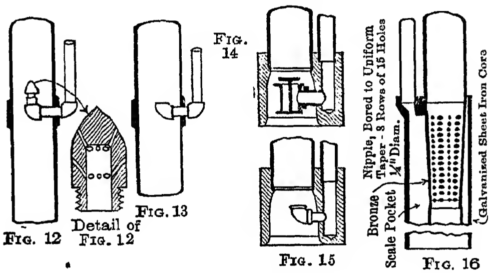
Diam. of Bubble (approx.) in........	0.05	0.10	0.125	0.15	0.25	0.38
Velocity of Rise, ft. per sec..........	0.53	0.57	0.67	0.70	0.80	0.81

The relative decrease in the rate of rise with the larger bubbles appears to be due to surface tension and to the flattening of the larger bubbles.

EFFICIENCY OF THE AIR-LIFT. (A. W. Purchas, *Proc.* Inst. M. E., Nov. 1917.)—An efficiency of 70% for all lifts up to 300 ft. may be assumed. This efficiency may not be attained with the first eduction pipe installed, which usually is put down to find the service pumping level and capacity of the well, and is not the final one. Two measures of efficiency are used: Overall efficiency, which includes the efficiency of the compressor; and eduction pipe efficiency. Let E_a = overall efficiency, E_p = efficiency of

eduction pipe, $A.Hp.$ = energy contained in the air at footpiece, $I.Hp.$ = indicated horsepower in air cylinders of compressors, and $W.Hp.$ = horsepower required to raise the water delivered by the pump. Then $E_a = W.Hp./I.Hp.$, and $E_p = W.Hp./A.Hp.$ The low efficiencies shown by earlier air-lift pumping plants probably was due to imperfect design and to inaccuracies in measurements of air used. Tests based on volumetric efficiency of the air compressor, the basis of nearly all earlier tests, probably were inaccurate, as this method of determining quantity of air supplied usually has a large percentage of error. In later tests the air has been measured by an orifice, with an accuracy within 2%.

FOOT-PIECES.—A. W. Purchas (*Proc.* Inst. M. E., Nov., 1917) says that design of foot-piece has small effect on efficiency of the pump if the fundamental laws of losses in transmission of air and water are followed in design, and if the air is injected in small bubbles. Attempts to use the injector principle are useless. Throttled air and water passages, and back pressure on the air lines generally result. Figs. 12 to 17 show



Foot Pieces for Air-lift Pumps

foot-pieces used in tests described in the paper. Those in Figs. 12 to 15 contract the water passage; those in Figs. 13 and 15 tended to become choked with rust and scale. The following points are desirable in foot-piece design: Avoid loss of air pressure in transmission from well-head to foot-piece; keep air pipe outside of eduction pipe; provide a pocket for rust and scale forming in the air pipe, which will prevent its lodging in the foot-piece; introduce air in the smallest bubbles possible; provide orifices that will not corrode and choke; proportion water passages so that there will be no sudden changes in velocity of the rising column. These conditions are filled by foot-pieces, Figs. 16 and 17.

PERFORMANCE OF AIR-LIFT PUMPS.—*Eng. News*, June 18, 1908, describes tests of 11 wells at Atlantic City, N. J. The wells were 10 in. diameter; water pipes, 4 to 5 1/4 in.; air pipes, 3/4 to 1 1/4 in.; maximum lift, 26 to 40 ft.; submergence, 37 to 49 ft.; submergence ratio, 0.9 to 1.8;

Table 11.—Tests of Air-Lift Pumps in California Oilfields

1. Lift when pumping, ft	295	297	302	312	314

Pumping efficiency, %	9.3	13.4	19.5	10.3

A. W. Purchas (*Proc.* Inst. M. E., Nov., 1917) describes tests on air-lift pumps forming the water supply system of the California Oilfields, Ltd., in Coalinga district, California. The foot-piece shown in Fig. 16 was used in these tests. Air pressure at compressor ranged from 132.5 to 136.4 lb. per sq. in. The results of the tests are given in Table 11.

Average practice (1935) is given by Worthington Pump & Machinery Corp. as follows:

Total lift, ft.	20–100	100–150	150–350	350–550	550–750
Submergence ratio, %	70– 50	65– 50	65– 50	50– 40	45– 30
Approximate air consumed, cu. ft. free air per gal. of water	0.21–0.55	0.45–0.70	0.55–1.30	1.30–2.30	2.30–3.65

Higher lifts and less submergence sometimes can be used.

The capacity of air-lifts may be taken as follows:

Water Pipe Diam., in.	Average Capacity, gal. per min.	Water Pipe Diam., in.	Average Capacity, gal. per min.
3	40– 80	8	500– 600
4	80–120	9	600– 700
5	140–200	10	700– 800
6	200–400	11	800– 900
7	400–500	12	900–1000

A pump for acid mine water (John S. Owens, *Engg.*, Sept. 23, 1921) has two stages, the first from the 210- to the 180-meter floor; the second from the 180- to the 150-meter floor. The foot-piece used, shown in Fig. 16, was designed to provide an unobstructed passage of water, to keep the size of bubbles at a minimum, to arrange for uniformity of pressure at top and bottom of foot-piece by means of a Venturi throat, so that air distribution could be controlled, and to avoid a sudden increase in the velocity at the foot-piece. The Venturi-throat-piece was perforated with from 550 to 600 ¼-in. holes. The angle of opening of the upper part of the throat did not exceed 5°. The diameter at the throat was made such that loss of head due to velocity at throat would somewhat more than balance static head due to increased depth at throat. The holes were drilled in rings around the throat, the number increasing toward the top, so that air was admitted in an increasing volume as velocity of water increased. Table 12 gives result of typical tests of this pump.

7. VACUUM PUMPS

THE PULSOMETER raises water by suction into the pump chamber by condensing the steam within it. The water then is forced into the delivery pipe by the pressure of a new quantity of steam on the surface of the water. Two chambers are used, one raising while the other discharges. Maximum suction lift is about 25 ft., the best working range being 7 to 15 ft. The discharge head may be as high as 150 ft. Steam pressure may be at least 50% higher than total water pressure.

DeVolson Wood (*Trans.* A.S.M.E. xiii) describes a test of a pulsometer 40 in. high, weighing 695 lb. Suction pipe, 3½ in. diam.; steam pipe, 1 in. diam. Table 13 gives the results of four tests.

Table 13.—Test of a Pulsometer

Efficiency of pulsometer	0.012	0.0155	0.0126	0.0138
Efficiency of plant exclusive of boiler	0.0093	0.0136	0.0115	0.0116
Efficiency of plant if that of boiler be 0.7.	0.0065	0.0095	0.0080	0.0081
Duty, if 1 lb. evaporates 10 lb. water	10,511,400	13,391,000	11,059,000	120,36,300

A very high record of test of a pulsometer is given in *Engg.* Nov. 24, 1893. Height of suction, 11.27 ft.; total lift, 102.6 ft.; horizontal length of delivery pipe, 118 ft.; quantity delivered per hr., 26,188 British gal.; steam used per Hp.-hr., 92.76 lb.; work done per lb. of steam, 21,345 ft.-lb., equal to a duty of 21,345,000 ft.-lb. per 100 lb. coal if 10 lb. of steam be generated per pound of coal.

THE JET-PUMP works by means of the tendency of a stream or jet of fluid to drive or carry contiguous particles of fluid along with it. Capacities range up to about 700 gal. per min. In some experiments on a small scale, greatest efficiency of a jet-pump was when the depth from which the water was drawn by suction was about 0.9 of the height from which the water fell to form the jet. The flow up the suction pipe then was about $^1/_5$ that of the jet, and the efficiency consequently was $0.9 \times {}^1/_5 = 0.18$. This efficiency is low, but probably could be increased by improvements in proportions of the machine. The preferable height of suction should not exceed 15 ft.

THE INJECTOR when used as a pump has a very low efficiency. See p. 6–59.

8. THE HYDRAULIC RAM

The hydraulic ram is used where a considerable flow of water with moderate fall is available to raise a small portion of the flow to a height greater than the fall. It acts on the principle of water-hammer. The water in the pipe line (drive-pipe) escapes through a weighted "clack-valve." The velocity of flow through the valve is sufficient to lift and close the valve, whereupon the momentum of the water in the pipe line sets up sufficient pressure to force water past a check valve into an air chamber. As the excess pressure falls in the pipe line, the clack-valve reopens and the cycle repeats. When sufficient pressure has been built up in the air chamber, the water in it discharges through an outlet pipe.

Let Q = total water supplied to ram; q = quantity delivered by ram, both in cu. ft. per sec.; H = head on ram, ft., h = height above pond to point of delivery, L = length of drive-pipe, from pond to clack valve, ft., D = diameter of drive-pipe, ft. Then $D = \sqrt{1.63Q}$; L (minimum) $= 5h$ or $^3/_4\ (H + h)$.

Volume of air chamber = volume of delivery pipe.

Efficiency $= q\,(H + h)/QH$.

Efficiency depends on ratio of lift to fall. Clark gives the following figures:

Ratio lift to fall	4	6	8	10	12	14	16	18	20	22	24	26
Efficiency, percent.	72	61	52	44	37	31	25	19	14	9	4	0

L. F. Harza (*Bull.* 205, Univ. of Wis., 1908) reports tests of a Rife "hydraulic engine." Length of 2-in. drive-pipe, 85.4 ft. Supply head, H = 8.2 ft. Maximum velocity V in drive-pipe, ranged from 1.5 to 6 ft. per sec. Efficiencies were as follows:

h, ft.,	v = 1.5	2	3	4	5	6
2.6	..	30	20	15	7	0
12.3	60	60	45	33	18	0
23.2	60	65	53	40	20	0
43.5	55	60	53	42	30	0
63.1		60	55	50	28	0

Four tests by Prof. R. C. Carpenter (*Engg. Mechanics*, 1894) to determine length of stroke of clack-valve giving highest efficiency, showed highest efficiency at 60% travel, full travel being 15/16 in. The $1\frac{1}{2}$-in. supply pipe was 50 ft. long with 3 elbows. Supply head H ranged from 5.58 to 5.77 ft. Delivery head h was constant at 19.75 ft. Results of the tests were as follows:

Length of stroke, percent	100	80	60	46
Strokes per min	52	56	61	66
Total water pumped, lb.	297	296	301	297.5
Total water supplied, lb	1615	1567	1518	1455.5
Efficiency, percent	64.9	66.0	74.9	70.0

Four rams were tested by the Columbia Steel Co., Portland, Ore., 1908. Results are shown below. L = length, ft., and D = diam., in., of drive-pipe; l and d = length and diameter of delivery pipe; H = head on ram, ft.; h = height of lift above original source of supply; Q and q = respectively water supplied and delivered, gal. per min.

Size of Ram	H	$(h+H)$	Q	q	L	D	l	d	Effic. %
3-in.	4	28	35	3.5	28	3	1008	1 1/2	58.9
4 1/2-in.	5	45	100	8	40	4 1/2	325	....	72.0
6-in.	12	36.4	200	50.5	60	4 1/2	945	2 1/2	76.6
6-in.*	37.6	144.1	2809	516	192.5	6	1785	10 *	70.4

* Eleven rams discharge into one 10-in. jointed wood pipe. Loss of head in drive pipe, 0.7 ft.; in discharge pipe, 2.7 ft. On one test, 1 cu. ft. per sec. was delivered with less than 5 cu. ft. entering drive pipe; at 5 cu. ft. efficiency = 76.6%.

CENTRIFUGAL PUMPS

By V. deP. Gerbereux

A centrifugal pump comprises essentially an impeller or set of vanes enclosed in a housing or casing. Fundamentally, it adds energy in the form of velocity to an already flowing liquid; it does not, in the usual sense, add pressure. All basic considerations of the centrifugal pump must consider kinetic energy; all relations must be expressed in linear measure.

THE THEORY OF THE CENTRIFUGAL PUMP is developed from the common kinetic energy relation (law of falling bodies),

$$\{H_a + (V_a^2/2g)\} = \{H_b + (V_b^2/2g) + H_F\}.$$

Various authorities differ as to the development of the theory from these relations and much of the design is based on empirical constants developed by test. Figs. 1 and 2 illustrate a simple generally accepted consideration of the theory. Fig. 1 is a vector diagram of the exit of a centrifugal pump impeller. With zero speed at impeller intake, head energy is found to be the product of CU_2, *i.e.*, the tangential component of C_2 (or CU_2) and of U_2, whence $H = (CU_2U_2)/g$. With zero flow $CU_2 = U_2$, and theoretical head is $H = U_2^2/g$. As the quantity flowing increases, CU_2 decreases in value and the theoretical curve shown in Fig. 2 is obtained. This curve is based on a 100% transfer of energy and an infinite number of vanes of zero thickness. Practically, vane losses and shock losses occur at greater or less capacities than those for which the impeller has been designed. Fig. 2 shows how these losses affect the theoretical curve to produce the actual curve.

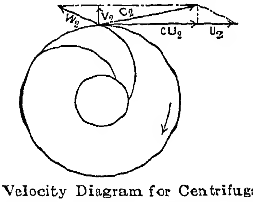

Fig. 1. Velocity Diagram for Centrifugal Pump

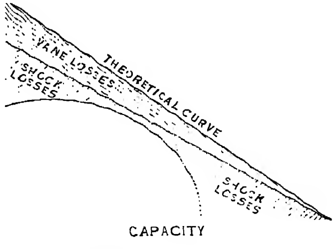

Fig. 2. Losses in a Centrifugal Pump

For actual pumping there must be an appreciable inlet speed; at the point where the liquid enters the impeller the inlet diagram is similar to Fig. 1. The theoretical head which the pump will deliver is $H = (CU_2U_2/g) - (CU_1U_1/g)$, and the theoretical head

at no flow in Fig. 2 would be $(U_2^2 - U_1^2)/g$ instead of U_2^2/g. The liquid leaving the impeller goes through a diffusion vane or a volute which converts into head energy most of the kinetic energy imparted by the impeller.

USEFUL APPROXIMATE RELATIONS for the selection or application of centrifugal pumps are:

Impeller diameter $D = (1840K_u\sqrt{H})/\text{r.p.m.}$, where K_u is a constant varying from 0.9 to 1.15 for various types of impellers.

At constant impeller diameter, $\dfrac{\text{Capacity } A}{\text{Capacity } B} = \dfrac{\text{r.p.m. } A}{\text{r.p.m. } B} = \dfrac{\sqrt{\text{head } A}}{\sqrt{\text{head } B}}$.

At constant r.p.m., $\dfrac{\text{Capacity } A}{\text{Capacity } B} = \dfrac{\text{Impeller diam. } A}{\text{Impeller diam. } B} = \dfrac{\sqrt{\text{head } A}}{\sqrt{\text{head } B}}$.

POWER REQUIREMENTS.—Besides vane and shock losses a centrifugal pump has the following hydraulic losses: Internal leakage, stuffing box leakage, entrance losses,

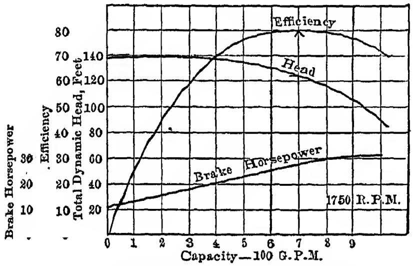

FIG. 3. Characteristics of Straight-vane Backward-angle Impeller

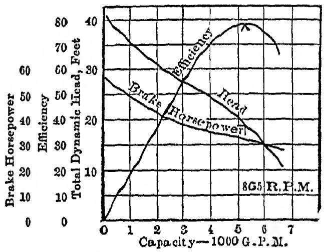

FIG. 4. Characteristics of Low-head Screw-vane Impeller

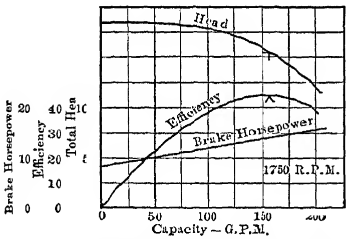

FIG. 5. Characteristics of Extreme Straight-vane High-head Impeller

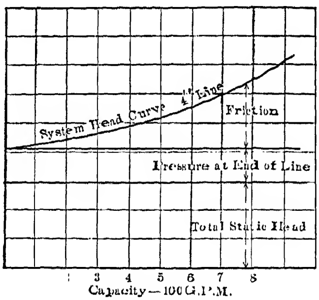

. 6. System Head Curve

impeller entrance losses and conversion losses. Mechanical losses comprise casing friction, disc friction, stuffing box friction and bearing friction. The power required is the fluid horsepower $wh/33000$ plus power losses, or fluid horsepower divided by efficiency.

Useful formulas are:

B.Hp. = (gal. per min. $\times H_t \times$ specific gravity)/(3960 $\times E$)

= (gal. per min. $\times$ lb. per sq. in.)/(1715 $\times E$), where H_t = total head, ft., and E = efficiency expressed as a decimal.

THE CHARACTERISTICS OF A CENTRIFUGAL PUMP generally are shown in the form of curves. Head, efficiency and horsepower usually are ordinates, with capacity as abscissa at constant speed. The shape of the various curves depends on the type of impeller used. Centrifugal pumps are classified as to type by their specific speed, N_s, which is calculated from head, capacity and r.p.m. by the formulas:

On the cu. ft. basis, $N_s = (\text{r.p.m.}\sqrt{\text{gal.}}$

On the gal. per min. basis (G.P.M.), $N_s = (\text{r.p.m.}\sqrt{\text{gal. per min.}})/H^{3/4}$.

Any two centrifugal pumps having the same specific speed type will have like characteristics. This fact is used in the design of large pumps, as small size models can be made to predict the performance of larger sizes. The application of the laws of similitude as applied to hydraulics makes it possible to design the larger pump accurately by factoring the dimensions of the small model.

Fig. 3 shows characteristics of the most usual type of straight-vane backward-angle impeller which is non-overloading. This would have a specific speed of 58 on the cu. ft. basis or 1230 on the GPM basis. Fig. 4 shows characteristics of the low-head higher speed type of screw or Francis vane impeller having a specific speed of 327 on the cu. ft. basis or 6880 on the GPM basis. Fig. 5 shows the extreme straight-vane high-head impeller characteristics. The specific speed here would be 24.3 on the cu. ft. basis and 514 on the GPM basis.

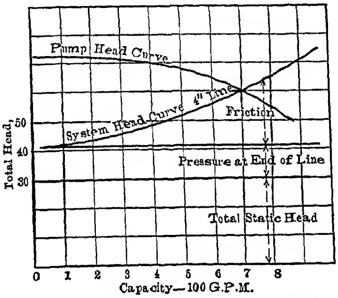

FIG. 7. Application of Pump to System Head Curve

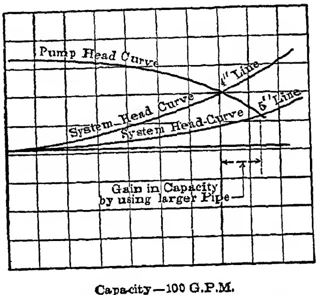

FIG. 8. Effect of Using Larger Piping

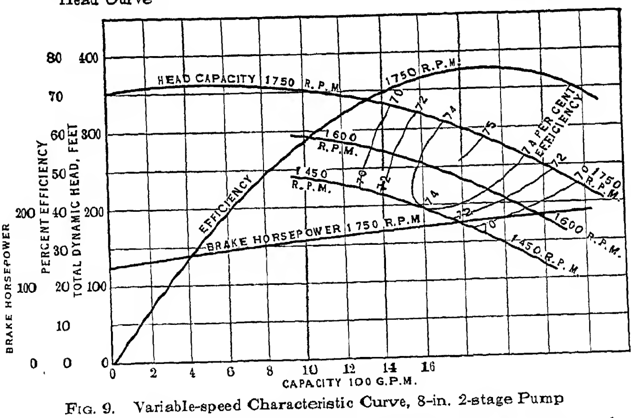

FIG. 9. Variable-speed Characteristic Curve, 8-in. 2-stage Pump

The application of a centrifugal pump to a pumping problem generally can be worked out graphically by plotting the system head curve in Fig. 6, then applying the head curve of the pump to the conditions, as shown in Fig. 7. If, in the future, additional capacity may be required a larger pipe could be used. See Fig. 8. Fig. 9 shows the effect of speed variation on the characteristics of a centrifugal pump.

The shape of the head-capacity curve can be varied within limits by variation in the impeller and casing design. For general service a curve similar to Fig. 3 is most satisfactory. Some services, where the head varies and the capacity should remain constant, require a *steeper* characteristic; others, as sprinkler or air washing service, require a *flatter* characteristic which keeps the head practically constant over a wide range of capacity. Boiler-feed pumps which generally must parallel require *steady* rising curves to as close to shutoff as design permits.

CLASSIFICATION.—Centrifugal pumps are classified into types and classes depending on: 1. The shaft position; 2. Number of stages; 3. Impeller arrangement; 4. Type

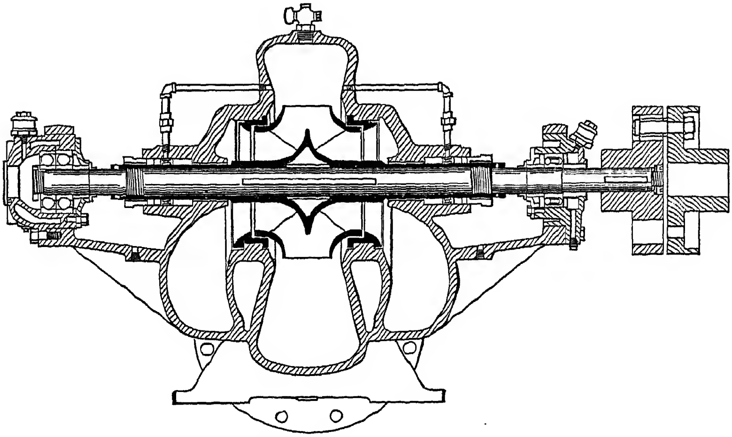

Fig. 10. Single-stage Double-suction Volute Pump

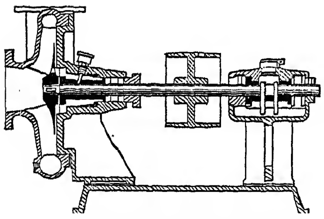

Fig. 11. Single-stage Single-suction Volute Pump

of drive; 5. Service for which they are designed. Table 1 shows the groups used commercially. The most common types are the horizontal single-stage double-suction volute pump for general service, Fig. 10; the single-stage single-suction volute, Fig. 11; and the multi-stage single-suction turbine, Fig. 12.

The Nominal Size of a Centrifugal Pump is the diameter of discharge opening. Some manufacturers give sizes as 6 × 8 meaning 6 in. discharge and 8 in. suction opening. It is not good practice to specify the nominal size of a centrifugal pump for a given capacity, as two equally reliable and efficient pumps for the same capacity

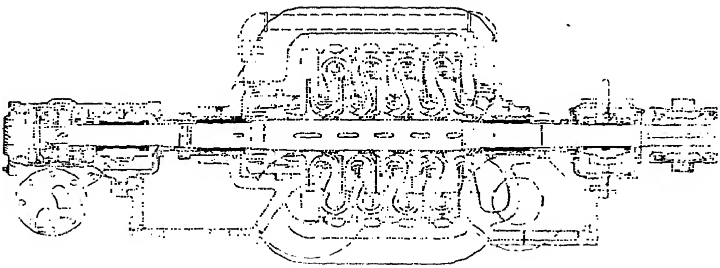

Fig. 12. Multi-stage Turbine Centrifugal Pump

and head would have different size openings according to the particular manufacturer's range of sizes.

Centrifugal pumps are available in sizes from 1/4-in. to over 100-in. nominal discharge, but all sizes over 36-in. are designed to order. Few manufacturers stock parts for sizes over 12-in. pumps. Centrifugal pumps also are available for heads from 5 ft. to over 2000 lb. per sq. in.

SUCTION LIFT.—Centrifugal pumps usually are designed for 15 ft. total dynamic suction lift. Any increase of suction lift (or decrease of absolute pressure available at suction opening of pump) will tend to decrease capacity of the pump. See Fig. 13. This is due to lack of available energy on the suction to create sufficient entrance velocity into the impeller. A pump operating with excessive suction lift is likely to be subject to cavitation and air binding, to be noisy in operation, and to wear rapidly. Centrifugal pumps can be designed for higher suction lifts than 15 ft. (usually at a lower r.p.m.), but only at a sacrifice of pump efficiency. Fig. 14 shows the limits of specific speed and suction lift agreed on as good practice by members of the Hydraulic Institute. Centrifugal pumps handling volatile liquids must be considered in the same class as pumps having a high suction lift.

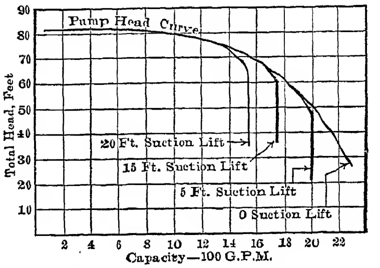

Fig. 13. Effect of Suction Lift

A centrifugal pump pumping a viscous liquid will show a loss of head and an increase in power required. Fig. 15 shows the effect of viscosity on a double-suction single-stage pump. In general, the centrifugal pump should not be used for viscosities over 1500 Saybolt Universal Seconds unless the capacity is over 2000 GPM, although this limit is fixed only by the extremely great decrease in efficiency with higher viscosities.

Uses of Centrifugal Pumps

GENERAL SERVICE PUMPS.—The so-called general service type of centrifugal pump comprises the horizontally-split case, double-suction volute, Fig. 10, the horizontally-split case single-suction volute, Fig. 11, and the multi-stage volute pump, Fig. 16. This service involves innumerable installation problems in the field of water supply, drainage, industrial and chemical plants. The pumps generally are considered as water pumps, and are standard fitted, *i.e.*, cast-iron casing, bronze impeller and bronze-covered steel shaft. The latest developments in this field are the monobloc pump (pump and motor built with a common shaft), and the use of automatic or self-priming (pump primed by automatic apparatus). Table 2 gives ratings and power requirements for general service pumps up to 5000 GPM and 440 ft. head.

BOILER-FEED PUMPS generally are multi-stage single-suction volute pumps, Fig. 16, for pressures up to 400 lb. per sq. in., and multi-stage single-suction turbine pumps, Fig. 12, for pressures of 200 to 1000 lb. per sq. in. For extreme pressures, pumps of similar design to Fig. 12 are used, but they are built heavier and in either vertically-split or solid-barrel type casings of cast steel or steel forgings.

Table 1.—Classification of Centrifugal Pumps

	Volute Pumps	Turbine Pumps
Shaft Position	Horizontal * Vertical	Horizontal * Vertical

* Most common.

In general, boiler-feed pumps are selected for 5 to 25% greater pressure than the rated boiler pressure, and for at least 200% of the rated boiler capacity. Common practice, where the size of boiler permits, is to use several pumps in parallel to permit variation of capacity without too great a loss in efficiency. In this case, all pumps operating on the same system should have similarly-shaped characteristic curves and a steady rising characteristic. As centrifugal pumps for boiler-feed service often have steam turbine or dual drive the rising characteristic is desirable as it also permits closer regulation of the capacity by speed variation.

* Diameter, in., of discharge opening, nominal size. † Recommended motor rating for pumping water.

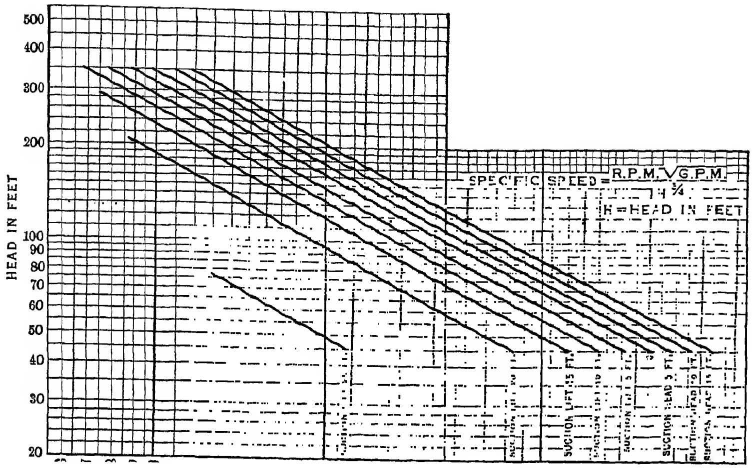

Fig. 14. Upper Limits of Specific Speed for Double-suction Single-stage Centrifugal Pumps

Centrifugal boiler-feed pumps usually pump preheated water, and the water should come to the pump under a positive head. For water at 212° F., centrifugal boiler-feed pumps should be installed with a minimum of 12 ft. submergence.

Table 3 gives ratings of standard boiler-feed pumps.

HOTWELL PUMPS.—Centrifugal condensate, or hotwell, pumps are generally multi-stage volute pumps, although the single-stage volute pump is used for low-head work. These pumps take their suction from a vacuum and usually pump water which is just below its vaporization point. They

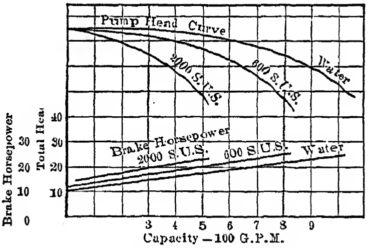

Fig. 15. Effect of Viscosity

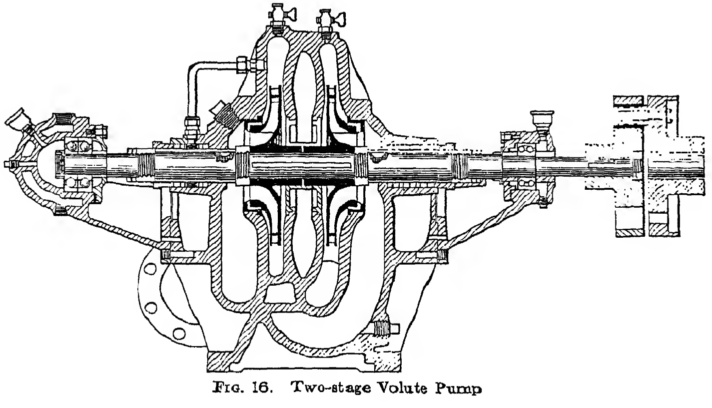

Fig. 16. Two-stage Volute Pump

are designed for extremely low suction velocities and generally low rotative speeds. The capacity which a given pump can deliver depends on the submergence available. Provision must be made to seal the stuffing box on the suction side to prevent air leakage and to vent the high spot of the suction passage to the vapor space above the hotwell.

Calculation of the total head must include vacuum in the condenser, plus the discharge pressure less the submergence on the suction, plus the suction pipe losses. In general 10% excess head should be allowed to steady the operation of the pump. The power required by a hotwell pump in actual operation cannot be measured on a cold water test due to the fluctuation in capacity and presence of vapor in the water. The efficiency of a given pump will be 5 to 10% less on hotwell service than on cold water service, which should be considered in selecting the driver.

SEWAGE AND SUMP PUMPS can be divided into two classes, the raw sewage pump (including sludge pumps), and the storm water pump. The latter is properly a drainage pump. Centrifugal pumps for pumping unscreened or partially screened sewage generally are single-stage volute, end suction pumps, either horizontal or vertical shaft. They usually are fitted with non-clogging type impellers which will pass solids of diameter 1 in. less than that of the discharge opening of the pump. Greater pump efficiency can be obtained if the pump is not required to pass the maximum size solids. Table 4 gives ratings of standard sewage type pumps. Centrifugal pumps can pump sewage sludge only when the sludge is sufficiently fluid to flow readily in the pump. The pump selected for sludge pumping should have extremely low velocities throughout.

* Diam., in., of discharge, nominal size. † Recommended motor rating for boiler-feed service.

Vertical shaft pumps can be either dry pit or submerged; installation cost on the former is higher but it is accessible and easily maintained. The wet pit type can be mounted on a drop pipe supported from the motor floor, which makes it possible to remove the entire pump through the pit cover. See Fig. 17.

Sump pumps can be of the non-clogging type similar to the wet pit sewage pump, or can have a normal open or closed centrifugal impeller instead. The axiflo type, using a propeller wheel, makes a simple low cost unit.

IRRIGATION AND DRAINAGE PUMPS.—The centrifugal pump originally was designed to handle large quantities of water at low heads. One of its first uses was in the irrigation and drainage field. Earlier pumps were end-suction, single-stage volute pumps running at low speeds, direct connected or belted from steam engines. The use of double-suction pumps increased rotative speed, but due to the low heads, 15 to 30 ft., were also inefficient and expensive. Two main types are now in service, the propeller type, Fig. 18, and the mixed flow or screw type, Fig. 19. These are high specific speed types, having characteristics similar to Fig. 4, and run at relatively high speed. They are suitable for direct connection to Diesel engines and synchronous motors. Vertical pumps of both types often are used. The vertical axiflo propeller pump, Fig. 20, is the most common type for this service.

REFINERIES AND PIPE LINES.—Centrifugal pumps, extensively used in oil refineries, must be selected with consideration of the physical characteristics of the liquid handled, *viz.*, viscosity, specific gravity, temperature, vapor

* Diameter, in., of discharge, nominal size. † Recommended motor rating.

pressure and the presence of grit, coke or foreign material. For non-volatile liquids at temperatures under 200° F., the so-called standard type of centrifugal pump often is used. As temperatures and pressures increase, special design features are required. Fig. 21 is a typical refinery pump with water-cooled stuffing boxes and bearings, vent

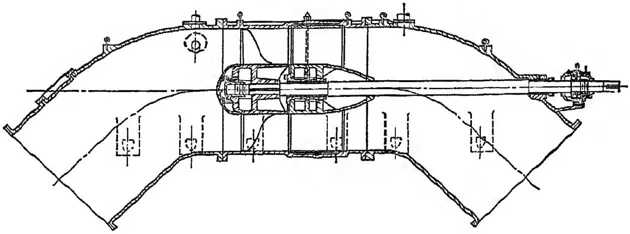

Fig. 18. Propeller Pump

connections and other features. Good practice uses cast or forged steel for pump casings subject to high pressures and temperatures over 450° F. Other special materials, as stainless steel and Monel metal often are required to withstand the action of the liquid and temperature. Multi-stage turbine pumps with forged steel barrel-type casings have been used for temperatures up to 1000° F. and pressures above 1500 lb. per sq. in.

Viscous Liquids reduce the output of a centrifugal pump and also reduce its efficiency. For pumps with 10-in. discharge and smaller, the maximum viscosity at which it is economical to use a centrifugal pump is 1500 Saybolt Universal Seconds.

Vaporizing Liquids require a careful study of suction conditions when selecting a refinery pump. It is imperative that sufficient submergence (static head on suction) be provided. Many refinery pump troubles are due to insufficient suction head.

Oil and Gasoline Pipe Lines require highly efficient, reliable centrifugal pumps. These are generally multi-stage volute pumps with loop inter-stage passages, designed for quick accessibility and repair. The prime mover usually is a squirrel-cage induction motor; Diesel or gas engines driving through step-up gears with ratios as high as 1 : 12 are not unusual. Usual station pressures

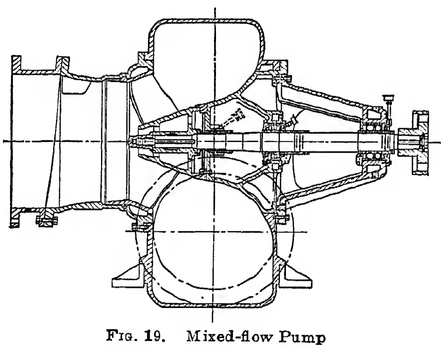

Fig. 19. Mixed-flow Pump

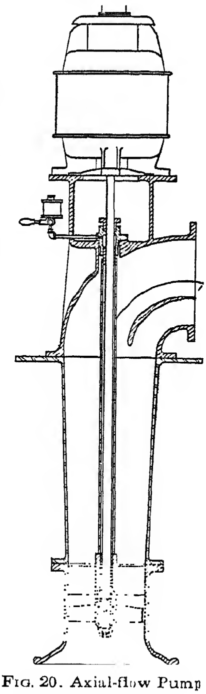

Fig. 20. Axial-flow Pump

are 800 to 900 lb. per sq. in., developed by a single pump or two pumps in series, depending on the flexibility required. Pump head curve should be matched against system head curve to obtain the best performance. Variation of viscosity of oil with temperature must be considered, together with the effect of this viscosity on both pump and system head curves.

PAPER MILLS.—Centrifugal pumps are used almost exclusively in paper mills. The principal services are general service, circulating, and boiler feeding.

The pumping of *paper stock* at consistencies as high as 8% (*i.e.*, 8% of solids) is common. The stock pump usually is an end-suction, single-stage, open-impeller pump, with the casing split on an angle to facilitate removal of the upper half without disturbing pipe connections. The bronze impeller must be of such design as will prevent dewatering of stock.

To pump various *acids and alkali solutions* in the paper mill requires centrifugal pumps of special metals, as stainless steel. The pumps should be of the simplest possible construction, usually end-suction, single-stage, open-impeller type with rugged bearings, heavy metal sections and designed for low rotative speed and low velocities.

DEEP WELL PUMPS.—(See also p. 2–73.) The centrifugal deep well pump is generally a turbine pump with diffusion vanes instead of volute casings. Since the diameter of the well is limited, the head per stage generally is low, but the number of stages is limited only by the depth of the well and the shaft diameter necessary to transmit the power. Most deep well turbine pumps are driven by hollow shaft motors, arranged to carry the pump thrust, no pump thrust bearing being used. The driving head can be made with a thrust bearing for steam turbine or gear drive when required. In figuring total head, friction loss in the drop pipe and draw-down of the water in the well must be considered.

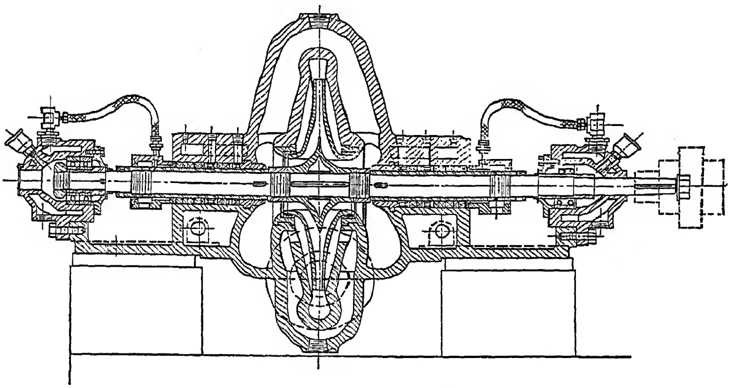

Fig. 21. Refinery-type Centrifugal Pump

FIRE PUMPS.—Centrifugal fire pumps are single or multi-stage, generally volute and designed to meet the requirements of the National Board of Fire Underwriters and the Factory Mutual Inspection Service, and have been approved by them. Table 5 gives typical ratings. *Booster pumps* are similar to fire pumps but for lower pressures, and no manifold is required. They also must be approved. *Tank filling* pumps are standard general service pumps of capacities up to 450 GPM and heads up to 231 ft., used for filling fire tanks. No special construction is required, but the pumps must be approved and listed.

Table 5.—Underwriter Centrifugal Fire Pump Ratings

For 100 lb. per sq. in. total head.

(Worthington Pump & Machinery Corp., Harrison, N. J.)

Pump Size, gal. per min.	No. of Stages	R.p.m.	Hp., Motor	Hp., Gasoline Engine	Diam. of Suction, in.	Diam. of Manifold Discharge, in.

500	1	3500	40	..	6	6
750	2	1150–1750	75	100	8	8
1000	2	1150–1750	100	125	8	8
1000	1	1700–1800	100	125	8	8
1500	2	1075–1750	150	168	10	10
1500	1	1700–1800	150	168	10	10

OTHER SERVICES.—Centrifugal pumps can be used for many services including contractors' service, with and without self-priming apparatus, jetting, in chemical plants.

breweries and distilleries, for refrigeration and air conditioning, and for marine work. The number of sizes, types and constructions is unlimited. Each field has a pump particularly adapted to it with the features required by that service. For example, contractors' pumps must be rugged and low in cost, brewery pumps must be quick cleaning, marine-type pumps must be light weight, etc. Manufacturers should be consulted for recommendations of the best type for a given service.

Installation and Operation

SELECTING LOCATION.—The pump should be easily accessible for inspection during operation. At the same time, the suction and discharge piping arrangement should be as simple as possible. In general, the pump should be located as close to the water supply as possible. Large size pumps should have head room for a crane or supporting structure sufficiently strong to lift the heaviest part of the unit. Motor-driven units should not be located in damp or moist places, unless special provision has been made for this condition.

SUCTION LIFT.—In ordinary pumping installation it is recommended that the suction lift should not exceed 15 ft. With warm water this must be reduced. Water at 212° F. must flow to the pump under net head of from 7 to 15 ft., depending on capacity at which pump is operating. Lift must be decreased or head increased 1 ft. for every 1000 ft. above sea level.

FOUNDATION.—The foundation should be heavy enough to afford permanent rigid support at all points of the baseplate and to absorb any normal amount of vibration that may develop from any cause. Concrete foundations built up from solid ground are the most satisfactory. In building the foundation ample allowance for grouting should be made. Foundation bolts of specified size should be accurately located from drawings or template and surrounded by a pipe sleeve, three or four diameters larger than the bolt. See Fig. 22.

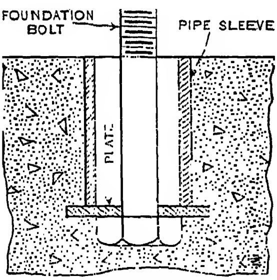

Fig. 22. Foundation Bolt

When the unit is mounted on steel work or other structure, it should be set directly over, or as near as possible to the supporting beams and walls and be so supported that the baseplate cannot be distorted and alignment disturbed by any yielding or springing of the structure.

ALIGNMENT.—Correct alignment is absolutely essential to successful operation. A flexible coupling is no excuse for misalignment. Its purpose is to eliminate transmission of end thrust from one machine to the other, and to compensate for slight changes in alignment that may occur during normal operation.

Factory Alignment.—Every unit that is assembled should be accurately aligned by the manufacturer, by placing the baseplate on a surface plate, leveling the machine pads, and shimming where necessary under pump and driver feet to obtain perfect alignment. Since all baseplates are elastic, no matter how deep or heavy they may be, shop alignment must be reproduced after the unit is erected on its foundation, to insure proper mechanical operation.

Field Alignment.—Pumps, with few exceptions, are shipped on their baseplates and it usually is unnecessary to remove pump and driver from the baseplate while leveling. The pumping unit should be placed on the foundation, supported by plates and wedges near the foundation bolts, allowing from 3/4 to 2 in. opening between bottom of baseplate and top of foundation for grouting. Coupling bolts, and one pump bearing cap, preferably on the inboard bearing, and the corresponding top half bearing bushing, should be removed. With a small spirit level on the pump shaft, the wedges under baseplate are adjusted to bring pump shaft level and pump nozzles into a true vertical plane. When the pump is level and at the desired position for piping connections, foundation bolts on the pump end should be pulled down sufficiently to hold pump in position.

During the above procedure little attention is given to the driver half of the unit; in most cases the coupling halves will be appreciably out of alignment. In any event the alignment must be checked and corrected by adjusting wedges under the driver end of the baseplate to bring driver and pump half couplings in perfect alignment. Alignment can be checked by a straight edge across the top and sides of the coupling, at the same time checking faces of the coupling halves for parallelism by a thickness gage or set of

feelers. See Fig. 23. When both couplings are perfectly true on both faces and outside diameters, exact alignment will show the distance between faces to be the same at all points, and a straight edge will lay squarely across the rims at any point. If the faces are out of parallel, the thickness gage or feelers will show a variation at different points. If one coupling is higher than the other the amount may be determined by the straight edge and feelers.

It sometimes may be found that couplings are not perfectly true and not the same diameter. In checking trueness of either coupling, revolve it while holding the other half stationary, checking alignment at each quarter turn of the half being rotated. Next revolve and check alignment of the half previously held stationary. If any variation is found in either of the half couplings, proper allowance must be made in aligning the unit.

Where pumps are driven by steam turbines which are subject to temperature changes in operation, final alignment should be made with the driver heated to operating temperature. If this is not possible at time of alignment, proper allowance should be made. Similarly, where the pump is subject to expansion in service, due to handling hot liquids, allowance must be made for expansion. In any case the cold alignment should be checked when hot, and adjusted as required before the unit is placed in service.

Clearance between coupling faces should be set so that they cannot strike, rub or exert pull on either pump or driver. The amount of clearance may vary with the size and type of coupling used. The best rule is to allow sufficient clearance for unhampered endwise movement of the shafts of either element to the limit of their respective thrust bearing clearances. On motor-driven units, the magnetic center of the motor will determine the running position of the motor half-coupling. It is well to check this point by operating the motor light before coupling bolts are replaced. If electric power is not available to operate the motor light, the motor shaft should be moved in both directions as far as bearings will permit, and shaft adjusted centrally between these limits, assembling the unit with the correct gap between coupling halves. Coupling bolts are not put in until piping is complete and driver has been tested for correct direction of rotation.

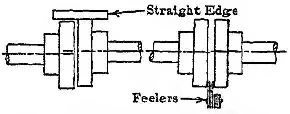

Fig. 23. Method of Aligning Pump and Driver

Alignment must be checked after the pump has been completely piped, as pumps are easily sprung and pulled out of position by drawing up bolts in piping flanges not brought squarely together before bolts are tightened. Suction and discharge piping should be so supported that they cannot exert a strain or pull on the pump. Pipe strains are a common cause of misalignment, hot bearings, worn couplings and vibration.

GROUTING.—The baseplate usually is grouted in before piping connections are made, but, in special cases, the reverse is permissible. The usual mixture for grouting a machine is one part pure cement, two parts sand, with sufficient water to cause the mixture to flow freely under the baseplate. A form should be built around the outside of the baseplate to hold the grout and provide sufficient head to assure a flow of the mixture underneath the entire baseplate. Grout should be allowed to set for 48 hours.

SUCTION PIPING.—By far the greater number of centrifugal pump troubles, outside of misalignment, can be traced to a faulty suction line. Suction piping should never be of less diameter than the full size of pump suction opening. It should be as short and direct as possible. Where a long suction line cannot be avoided, the size of the piping should be increased. Air pockets or high spots in a pump suction line invariably cause trouble. Piping must be so laid as to provide a continual rise without high spots from source of supply to pump. The suction pipe should be submerged when the water is at its lowest level, with the pump operating. Large pipes usually are submerged four times their diameter, while small pipes require from 2 to 3 ft. submergence. Suction pipes should be blanked off and hydrostatically tested for air leaks before starting.

Foot Valve.—A foot valve may be installed on the end of the suction pipe for convenience in priming or where the pump runs intermittently. The size and type of foot valve should be selected to avoid excessive friction loss through the valve. An ordinary swing check valve should not be used as a foot valve.

A Strainer should be placed in the suction pipe to prevent lodgment of foreign material in the impeller. It is important to take every possible precaution to protect the pump against clogging. Clear and free opening through strainer should be three to four times the area of the suction pipe. If the strainer is subject to frequent clogging, the suction pipe should be accessible. For large pumps, removable screens should be placed at the entrance to the suction well.

DISCHARGE PIPES should be installed with a check valve and gate valve near pump outlet. The check valve gives protection against excessive pressure or water hammer.

On units with no suction foot valve, a check valve eliminates the possibility of the pump running backward if the driver ceases to function.

JACKET PIPING.—If a thrust bearing is supplied, the jacket cooling water pipe should be so connected that the supply enters at the bottom and discharges from the top. For observing flow and regulating the amount of jacket water, it is good practice to pipe the discharge to an open flow into a funnel connected to a drain.

DRAIN PIPING.—All drain connections should be piped to a pump pit or suction well.

GLAND PIPING to each gland should have a valve to control the amount of water necessary to feed and seal each gland and to permit enough seepage to lubricate the gland.

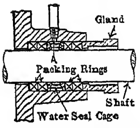

Fig. 24. Pump Packing

PACKING.—Square, soft, asbestos graphited packing, or equal, is recommended for either hot or cold service. Flax packing should not be used under any circumstances on centrifugal pumps having bronze shaft sleeves, as rapid wear of sleeves may result. To pack a centrifugal pump properly, rings should be cut slightly short, to prevent butting of the ends and buckling. Each ring should be inserted separately and pushed as far into the stuffing box as possible by means of the gland. The splits of each successive ring should be placed 90° apart. After two or three rings are inserted, the water seal cage should follow so as to bring it directly under the water pipe connections. See Fig. 24, at *A*. Enough additional packing then is inserted to allow the gland to be loosely drawn up.

WATER SEAL.—Stuffing boxes are water sealed to prevent air from leaking in and to keep the packing wet. A composition cage, in halves, inserted in the middle of the packing space is supplied with water piped directly from the discharge, if the pump handles clear, cold water.

Independent water sealing should be provided from an independent source of cold, clean water, at a pressure of 15 to 40 lb. under the following conditions: 1. On suction lifts of 20 ft. to 25 ft. Ordinarily operation above 15 ft. is not recommended. 2. When discharge pressure is less than about 10 lb., or 23 ft. head. 3. When pumps are handling water over 175° F. 4. When the water is muddy, sandy or gritty. 5. In general, when liquid handled is other than water, as acid, juice, molasses and sticky substances. 6. On all hotwell pumps.

PRIMING.—A centrifugal pump never should be operated unless filled with water. The pump cannot deliver water when operated dry, and wearing rings are likely to seize and cause serious damage. The only exception to this rule is a pump specially designed to start dry, and fitted with water-lubricated wearing rings whose water supply is from a source external to the pump.

With a foot valve on the suction pipe the pump can be primed by venting the high point of the pump casing and admitting water from an outside source until suction pipe and casing are completely filled. All air must be exhausted from suction pipe and pump casing, as any entrapped air will interfere with operation or hinder the pump from lifting water.

If the suction pipe has no foot valve, an ejector of good design and ample size, should be connected to the high point on pump casing. Ejectors can be operated with air, steam or water. With water, the supply must be of sufficient pressure to give high velocity through the ejector.

Priming is unnecessary if the suction supply is under sufficient head to fill the pump casing, which is vented at the high point to permit the water to expel entrapped air.

Another satisfactory method of priming is to use a motor-driven rotary vacuum pump. Several types, which will handle both air and water successfully, are available. If a dry vacuum pump is used for priming, the vacuum must be prevented from drawing over any water.

STARTING AND OPERATING.—Before starting the first time, the prime mover should be disconnected and tested for correct direction of rotation, as indicated by the arrow on the pump casing.

All bearings should be washed with kerosene, and oil rings should be free to turn. Bearings should be filled with a good grade of dynamo oil. After checking jacket cooling water piping on thrust bearings to make sure that inlet is at bottom and discharge at top, the supply may be turned on, allowing an ample flow to keep the bearing cool. The water seal supply to glands next is turned on and the pump primed. The pump should not be run unless primed and full of water, as interior parts which depend on water for lubrication may be injured. Careful final inspection should be made of all parts before starting, and then the pump may be brought to speed. After a pressure is built up on the discharge, the discharge gate valve should be opened slowly.

A compound gage and a pressure gage connected respectively to the suction and discharge of the pump, and mounted at a convenient place, will greatly help the operator.

During the routine operation of pumps, bearings should be occasionally inspected to insure that sufficient oil is in the oil pockets, and also that oil rings are turning freely and supplying enough oil to shaft and bearings. Bearings should be drained and washed, and the oil renewed every week or ten days during the first month of operation, and as often after that as conditions warrant.

Stuffing box glands must be so adjusted as to permit a slight seepage of water out of the stuffing box at all times during operation. Otherwise, the packing will cause excessive wear on shaft sleeves.

LOCATING TROUBLES.—The most common troubles, together with their causes, which may occur with a centrifugal pump are: 1. *Failure to Deliver Water.* *a.* Pump not primed. *b.* Insufficient speed. *c.* Discharge head too high. *d.* Suction lift too high (over 15 ft.); check with vacuum gage. *e.* Impeller plugged up. *f.* Wrong direction of rotation. 2. *Insufficient Capacity.* *a.* Air leaks in suction or stuffing boxes. *b.* Speed too low. *c.* Total dynamic head higher than that for which pump is rated. *d.* Suction lift too high (over 15 ft.); check with vacuum gage. *e.* Impeller partially clogged. *f.* Insufficient suction head for hot water. *g.* Mechanical defects, *i.e.*, wearing rings worn, impeller damaged, casing packing defective. *h.* Foot valve too small or restricted by trash. *i.* Foot valve or suction pipe not deeply enough immersed. 3. *Insufficient Pressure.* *a.* Speed too low. *b.* Air in water. *c.* Mechanical defects, *i.e.*, wearing rings worn, impeller damaged, casing packing defective. 4. *Pump Loses Water after Starting.* *a.* Leaky suction line. *b.* Water seal plugged. *c.* Suction lift too high (over 15 ft.). *d.* Air or gases in water. 5. *Pump Overloads Driver.* *a.* Speed too high. *b.* Total dynamic head lower than rating—pumping too much water. *c.* Liquid pumped of different specific gravity and viscosity than that for which pump is rated. *d.* Mechanical defects. 6. *Pump Vibrates.* *a.* Misalignment. *b.* Foundation not sufficiently rigid. *c.* Impeller partially clogged, causing unbalance. *d.* Mechanical defects, *i.e.*, shaft bent, rotating element binds, worn bearings.

DRIVERS.—The electric motor is the most common driver for the centrifugal pump. The low starting torque of the centrifugal pump (10 to 25% of full load) avoids complex problems and permits use of the standard squirrel-cage induction motor. Synchronous motors must be selected for a pull-in torque to match pump characteristics. Variable speed motors and two-speed motors are desirable for some types of installations. Motors selected can be rated for the actual pump brake-horsepower. The steam turbine, either direct-connected or geared, is a common driver for the centrifugal pump. It has the advantage of variable speed, easily regulated by steam flow. Steam turbines selected can be rated for the actual pump brake-horsepower. Internal combustion engines (Diesel, gas and gasoline) involve a little care in installation, particularly when step-up gears are used. Critical speeds should be avoided by the selection of flexible couplings which do not transmit torsional vibration. The engine should be selected for 25% greater rating than the pump brake-horsepower.

Water-wheels, when used as drivers for centrifugal pumps, must be accurately matched to the pump load. Both machines have similar torque-speed relations and a careful study of both is necessary to proper installation. The water-wheel-driven unit is simple to operate and control when properly installed.

The use of belts (excepting V belts) and steam engines as pump drivers is rapidly losing favor with a few exceptional cases. Both are relative low-speed drivers and therefore are not applicable to higher speed pumps. Flat belts should be selected for not over 4500 ft. per min. belt speed. Steam engines should be selected with 25% reserve horsepower.

TURBINE-DRIVEN PUMPS.*—Steam-turbine-driven centrifugal pumps have greater flexibility than motor-driven units. The speed may be readily adjusted through any range to obtain the desired head, while alternating-current motors have a limited number of steps in speed. It is often desirable and economical to operate large centrifugal pumps at speeds lower than the most economical turbine speed, using mechanical reduction gears with flexible couplings on both sides of the gear. Such geared turbines operate at speeds up to 7000 r.p.m. Speed ratios in reduction gears range, for single reduction sets, from 25 to 1 down to 3 to 1.

Geared turbine-driven centrifugal pumps have practically supplanted vertical triple-expansion and horizontal cross-compound pumping engines for steam-driven municipal pumping equipment. Geared pumps cost much less and require less space and attendance. With the steam pressures, temperatures, and vacua commonly used (1934), the

* Contributed by A. G. Christie.

efficiency of a turbine-driven pump can be made to equal the best performance of a triple-expansion engine where the power exceeds 500 Hp.

Turbine-driven centrifugal pumps for regular water supply can be fitted for fire service by providing a device to cut out the ordinary governor, and furnishing additional steam nozzles to be opened by hand. Turbine speed then increases and automatically delivers a greater quantity of water against the higher head needed for fire service.

Larger boiler-feed pumps exceeding 1500 GPM capacity may be gear driven. Other boiler-feed pumps are direct driven, as pump speed can be made high enough for direct connection with reasonable efficiency. These pumps have been made as small as 100 GPM at speeds of 6000 to 7000 r.p.m. Small turbine-driven feed pumps are used on some locomotives. The turbines generally operate non-condensing, the exhaust being used to heat feedwater.

Main feed pumps in central stations generally are motor-driven centrifugal pumps, but a turbine-driven pump is used for standby services. Centrifugal boiler-feed pumps cause no pulsations on the boiler feed lines, and usually have check valves on the discharge side. A turbine-driven boiler-feed pump has a limiting head against which it will discharge at constant speed. Excessively high pressures on boiler-feed lines thus are impossible. Such pumps, even in small sizes are much more economical of steam than direct-acting steam pumps.

Turbine-driven centrifugal pumps for direct connection are built for various speeds. For central station work, centrifugal boiler-feed pumps, practically always, run at either 1750 r.p.m. or 3500 r.p.m. depending on the size.

Standard governors for turbines driving centrifugal pumps are constant speed with an emergency overspeed trip. Either of two controls also may be used; *viz.*, regulators to maintain constant pressure on the discharge line or controls to maintain a constant differential pressure between feed line and boiler drum.

When hot water is furnished to the suction of a turbine-driven centrifugal boiler-feed pump, a positive excess of pressure is needed at the pump suction for a margin to cover inaccuracies in estimating entrance loss, pipe friction, velocity head and total lift.

METHODS OF MEASURING TEMPERATURE

REFERENCES.—Technologic Paper No. 170, U. S. Bureau of Standards, Washington. High Temperature Measurements, Burgess-LeChatelier, John Wiley & Sons, New York. Pyrometry: A Symposium, Am. Inst. Min. & Met. Engrs., New York. Practical Pyrometry, Ferry, John Wiley & Sons. Methods of Measuring Temperature, Griffiths, J. B. Lippincott & Co. Power Test Code, A.S.M.E., Part 3, Instruments and Apparatus. Pyrometry, W. P. Wood and J. M. Cork, McGraw-Hill.

The several methods of measuring temperature are: 1. Liquid-in-glass thermometers, in which the expansion or contraction of a liquid, as mercury, alcohol, etc., indicates change in temperature. 2. Bourdon tube thermometers, in which the expansion or contraction of a liquid or gas in a tube actuates a Bourdon spring, which moves an indicating pointer or a recording pencil in accordance with the change in temperature. 3. Resistance thermometers in which change in temperature changes the electrical resistance of a calibrated wire. 4. Thermocouple pyrometers, in which a change of temperature sets up electromotive force at the junction of two dissimilar wires. 5. Radiation pyrometers, which absorb radiation of all wave lengths from the body whose temperature is being measured, the temperature of which is determined by the temperature attained by the absorber in the pyrometer. 6. Optical pyrometers, which determine temperature by comparing the luminosity of the body whose temperature is being measured with the luminosity of a calibrated source. 7. Pyrometric cones, comprising a series of cones of refractory material, graded according to temperature. These are used by noting which one of the series softens and bends when exposed to the temperature being investigated. The ranges of these several methods of measuring temperature are given in Table 1.

Table 1.—Range of Various Methods of Measuring Temperature

Type of Instrument	Range, deg. F.	Limits of Error, deg. F.
LIQUID-IN-GLASS THERMOMETER		
Ordinary glass, mercury-filled	−35 to 750	0.5 to 7
Corning normal, Corning Borosilicate, Jena 16III, Jena 59III, mercury- and nitrogen-filled	−35 to 925	0.5 to 7
BOURDON TUBE THERMOMETER		
Liquid-filled type		
Alcohol-filled	−50 to 300	2 to 10
Mercury-filled	−38 to 1000	2 to 10
Vapor-pressure type		
Alcohol-filled	200 to 400	2 to 10
Ether-filled	100 to 300	2 to 10
Sulphur-dioxide-filled	20 to 250	2 to 10
Aniline	400 to 700	2 to 10
Gas-filled type		
Nitrogen-filled	−60 to 1000	2 to 10
RESISTANCE THERMOMETER	−400 to 1800	Depends on indicating instrument
THERMOCOUPLE PYROMETERS		
Base metal	300 to 2000	Depends on indicating instrument
Rare metal	300 to 2800	2 to 20.
RADIATION PYROMETER	1000 and up	20 to 30 for black body conditions
OPTICAL PYROMETER	1500 and up	15 to 35 for black body conditions
PYROMETRIC CONES	1100 to 3600	15 to 30 (approx.) in best makes.

1. TEMPERATURE SCALES

The ideal temperature scale, known as the thermodynamic scale, was defined by Kelvin as follows: " The absolute values of two temperatures are to one another in the proportion of the heat taken in to the heat rejected in a reversible thermodynamic engine, working with a source and a refrigerator at the higher and lower temperatures, respectively." The interval between the freezing and boiling points of pure water being as 100° C., gives the size of the unit degree. The scales in practical use are supposedly in

general agreement with the thermodynamic scale or differ from it by small known quantities.

The high temperature scale from 100° C. to about 1500° C. is defined by the expansion of nitrogen in the constant-volume gas thermometer. This scale varies from the thermodynamic scale by about 0.05° at 200° C., 0.3° at 600° C. and 1° at 1200° C. This thermometer is employed only as a fundamental standard instrument to determine the number of so-called fixed points defined by the melting or boiling points of various chemical compounds and elements. Table 2 gives the fixed points utilized by the U. S. Bureau of Standards.

The limit of accuracy of the gas thermometer is 1550° C. Temperature scales beyond this point must be extrapolated by means of the Stefan-Boltzman or Wien-Planck radiation laws. The latter is $J = c_1\lambda^{-5}(e^k - 1)^{-1}$, where J = energy corresponding to wave length λ; T = absolute temperature of radiating black body; e = base of the natural system of logarithms; c_1 = constant depending on apparatus, distance from the source, etc.; c_2 = universal radiation constant = 14,330; $k = c_2/\lambda T$. The Bureau of Standards (Technologic Paper No. 170) has provisionally adopted the following means of defining the temperature scale: Interval −40 to +450° C. by the platinum resistance thermometer calibrated in ice, steam and sulphur vapor; from 450° to 1100° C. by fixed points of copper, antimony and zinc; above 1100° C. extrapolation of Wien's law, using the melting point of gold = 1063° C. and c_2 = 14,350. (See Optical Pyrometry, p. 3–12.)

2. THERMOMETRY

Liquid-in-Glass Thermometers

THE FAHRENHEIT THERMOMETER generally is used in English-speaking countries and the Centigrade, or Celsius, thermometer in countries that use the metric system. In many scientific treatises in English, however, the Centigrade temperatures also are used, either with or without their Fahrenheit equivalents. The Réaumur thermometer is slightly used in Continental Europe.

In the Fahrenheit thermometer the freezing-point of water is taken at 32°, and the boiling-point of water at mean atmospheric pressure at the sea-level, 14.7 lb. per sq in., is taken at 212°, the distance between these two points being divided into 180°. In the Centigrade and Réaumur thermometers the freezing-point is taken at 0°. The boiling-point is 100° in the Centigrade scale, and 80° in the Réaumur.

1 Fahrenheit degree	= 5/9 deg. Centigrade	= 4/9 deg. Réaumur.
1 Centigrade degree	= 9/5 deg. Fahrenheit	= 4/5 deg. Réaumur.
1 Réaumur degree	= 9/4 deg. Fahrenheit	= 5/4 deg. Centigrade.
Temperature Fahrenheit	= 9/5 × temp. C. + 32°	= 9/4 temp. R. + 32°.
Temperature Centigrade	= 5/9 (temp. F. −32°)	= 5/4 temp. R.
Temperature Réaumur	= 4/5 temp. C.	= 4/9 (temp. F. − 32°).

FORMULAS FOR TEMPERATURE CONVERSION.—To convert Fahrenheit temperatures to Centigrade temperatures, the Taylor Instrument Companies, Roches-

ter, N. Y., give the following formulas, which are based on the fact that the values of the readings on both Centigrade and Fahrenheit scales are the same at $-40°$.

To Convert Centigrade to Fahrenheit:

$$T_c = \{(T_f + 40) \times {}^5/_9\} - 40 = 0.556\ (T_f + 40) - 40.$$

To Convert Fahrenheit to Centigrade:

$$T_f = \{(T_c + 40) \times {}^9/_5\} - 40 = 1.8\ (T_c + 40) - 40,$$

where T_f and T_c are Fahrenheit and Centigrade temperatures, respectively.

TYPES OF LIQUID-IN-GLASS THERMOMETERS.—Thermometers may be classified by:

1. Expanding fluid. The fluids commonly used and their working range are as follows:

Fluid	Mercury	Alcohol	Toluol	Pentane
Working range, deg. F.	−30 to 925	−100 to 250	−150 to 120	−300 to 70

2. Form.—Etched-stem, either armored or unarmored; industrial, with metal bulb and scale case surrounding thermometer, either of the straight stem or angle stem types; enclosed scale in which the scale, of paper or glass, is enclosed in an outer tube surrounding the thermometer stem.

3. Glass.—Corning normal or Jena 16^{III} for ordinary and medium temperatures; Corning boro-silicate or Jena 59^{III} for high temperatures (above 750° F.).

4. Immersion.—Graduated for full immersion of thread of expanding fluid in stem, or for partial immersion. For high temperatures they usually are graduated for partial immersion.

RANGE AND ACCURACY OF THERMOMETERS.—The usual limits of error of good etched-stem thermometers totally immersed in a calibrating bath in comparison with standard thermometers are:

Working temp. range, °F.	−300 to 70	−35 to 32	32 to 300	212 to 600	600 to 925
Limits of error, °F.	1 to 2	0.5 to 1	1	2	6 to 7

If the thermometers are used in wells or if graduated for full immersion and only partly immersed, even though stem corrections are applied, the errors usually will be greater than those given above. Partial immersion thermometers usually will be less accurate than the limits above noted.

CORRECTION FOR EXPOSED STEM OF MERCURIAL THERMOMETER.—If a portion of the mercury column thermometer is exposed to atmospheric temperature, the bulb being at a different temperature, a correction K must be added to the observed temperature, unless the thermometer has been calibrated for the particular conditions under which it is used.

$$K = n\beta\ (T - t) \text{ for Centigrade thermometers,}$$
$$= 0.55555\ n\beta\ (T - t) \text{ for Fahrenheit thermometers,}$$

where n = number of degrees of exposed stem; β = apparent coefficient of expansion of mercury in the glass; T = observed temperature; t = mean temperature of exposed stem. For temperatures up to 212° F.; the Smithsonian Institution gives the following values of β:

Jena 16^{III} or Greiner or Friedrich resistance glass, $\beta = 0.000159$; Jena 59^{III}, $\beta = 0.000164$; for glass of unknown composition, take $\beta = 0.000155$.

CALIBRATION OF THERMOMETERS.—Thermometers may be calibrated by comparison with a standard or secondary standard thermometer, both being immersed in a bath which can be heated to a desired temperature range. A standard thermometer is one that has been calibrated by the U. S. Bureau of Standards. A secondary standard thermometer is one that has been calibrated against a standard thermometer. The thermometer may be calibrated degree by degree, or at wider intervals ranging as high as 50°, depending on accuracy desired and purpose for which the thermometer is to be used. The standard thermometer should be immersed in the bath to the same depth as when it was calibrated, and the other thermometer to the depth at which it will be used. Ample time should be allowed to permit the thermometer under test to attain the temperature of the bath, in order to compensate for difference in time lag between it and the standard.

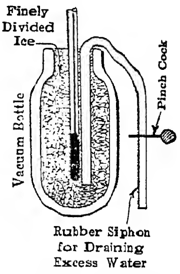

Fig. 1. Method of Determining Freezing Point

When calibrating by comparison with a standard thermometer, the temperature intervals can be made as small as desired if the bath has suitable control.

Another method of calibration is checking the fixed points, *i.e.*, freezing and boiling points on the thermometer.

3900	7052	7070	7088	7106	7124	7142	7160	7178	7196	7214

Examples: 1347° C. = 1340° C. + 7° C. = 2444° F. + 12.6° F. = 2456.6° F.
− 194° C. = − 190° C. + (− 4° C.) = − 310° F. + (− 7.2° F.) = − 317.2° F.
1852° F. = 1850° F. + 2° F. = 1010° C. + 1.11° C. = 1011.11° C.
− 226° F. = − 220° F. + (− 6° F.) = − 134.44° C. + (− 3.33° C.) = − 137.77° C.

Freezing Point is checked by surrounding the bulb with a mixture of water and ice, drawing off most of the water. The difference between the reading and the 32° mark on the thermometer is the error in location of the freezing point. In general, natural ice is satisfactory, but for a very high degree of accuracy ice made from distilled water should be used.

Boiling Point.—To determine boiling point, the thermometer is suspended in a bath so that it is entirely surrounded by the vapor of boiling distilled water at atmospheric pressure. Boiling should be continued until the water is free of air, which will be denoted by temperature indicated by the thermometer remaining constant, barometric pressure being unchanged. The thermometer should not project into the liquid. The difference between the thermometer reading and temperature as shown by the steam tables for the barometric pressure at which the test is made will be the error in the marking of the boiling point. Figs. 1 and 2 show types of apparatus recommended by the A.S.M.E.

Boiler Code Committee for determination of freezing and boiling points, respectively.

For temperatures up to 200° F. a water bath is satisfactory for comparison of thermometers. For temperatures from 200° to 600° F. an oil bath, using mineral or cylinder oil with high flash point, should be used. All baths should be stirred during tests to

maintain uniformity of temperature. For design of a satisfactory type of oil bath, see A.S.M.E. Power Test Code, Instruments and Apparatus, Part 3, p. 25, 1931. For tem-

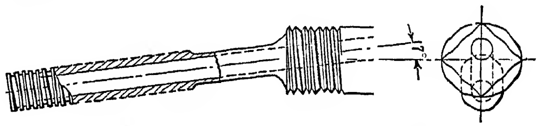

FIG. 5. Thermometer Well for Vertical Pipe

peratures between 300° and 900° F. molten salts, as Lavite, a mixture of barium and sodium chlorides, should be used. The type of bath should be similar to that used for oil.

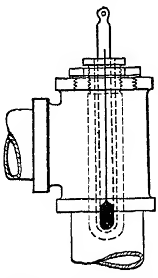

FIG. 6. Method of Inserting Well in Pipe

Time Lag.—A thermometer does not immediately indicate the temperature of the substance in which it is immersed. The time required to attain that temperature is known as the time lag and varies in different thermometers depending on a number of different conditions. In the measurement of temperatures of gases or liquids flowing in pipes the time lag may be of considerable importance, and the thermometer should be calibrated in respect to this feature. For a full discussion of time lag, see Thermometric Lag, U.S. Bureau of Standards Reprint No. 185.

THERMOMETER WELLS.—Whenever possible, a thermometer should be in direct contact with the substance whose temperature is being measured. When necessary to use a thermometer well, the well should not project any more than is necessary, in order to prevent heat transfer. All exposed parts of the well should be insulated, as should the wall of the pipe or other container for some distance on either side of the well, if such insulation will not affect the temperature of the substance being measured. The construction of the well should be such that it has the smallest possible metallic

connection, consistent with strength, with the wall of the pipe or other container, in order to reduce heat flow along the well. The well should have sufficient surface to enable it to absorb heat from the substance being measured as rapidly as it is lost from the exposed end.

The types of wells to be used to measure temperature of a fluid are as follows: Liquid and saturated vapor, plain well; gas and superheated vapor, finned well. Details of the construction of these wells are shown in Figs. 3 and 4, and in Table 5. Fig. 5 shows a finned well for a vertical pipe. Fig. 6 shows a method of inserting a well in pipes under 4 in. diam. For filling the wells mercury is advisable up to 500° F.; solder from 500 to 1000° F.; and tin from 600 to 1800° F.

Plain carbon steel (S max. = 0.05%) is suitable for wells for temperatures up to 750° F. For temperatures over 750° F. a heat-resisting steel should be used. The A.S.M.E. Boiler Code Committee gives (1931) the analyses of several steels that, with a proper factor of safety, may be used. Among these analyses are: 1. C, 0.49; Mn, 0.50; Si, 0.26; Cr, 1.62; Al, 1.00. 2. C, 0.50; Mn, 0.74; Si, 0.26; Cr, 2.32; V, 0.22. 3. C, 0.49; Mn, 0.24; Si, 0.26; Cr, 1.55; W, 2.40; V, 0.21. 4. C, 0.26; Mn, 0.65; Si, 3.03; Ni, 24.13; Cr, 18.23.

Bourdon Tube Thermometers

Bourdon tube thermometers are: 1. Liquid-filled, the liquid completely filling the bulb, capillary and spring. 2. Vapor pressure, the liquid in the bulb having a free surface. 3. Gas filled, the gas completely filling the bulb, capillary and spring. Bourdon tube thermometers may be used as indicating and recording instruments and also as distant-reading instruments.

LIQUID-FILLED THERMOMETERS are: 1. Non-compensated; 2. Compensated for change in temperature of spring only; 3. Compensated for change in temperature of spring and capillary. The liquids used usually are mercury for temperature ranges of −38° to 1000° F., and alcohol for temperature ranges of −50° to 300° F. The maximum length of capillary without compensation is 25 ft.; 10 ft. is the recommended maximum length. This type of thermometer uses bulbs smaller than those in the gas-filled and vapor-pressure types, and its accuracy is unaffected by barometric pressure changes.

VAPOR-PRESSURE THERMOMETERS depend for their action on the pressure inside the thermometer as determined by the temperature of the free surface of the liquid. If the capillary and pressure spring contain only vapor, error due to variation of temperature in tube and spring is absent. If the capillary and spring are filled with liquid no error will result from temperature change around the spring and along the capillary if the bulb temperature is higher.

The following liquids are used in vapor-pressure thermometers:

Liquid	Working Range, deg. F.	Liquid	Working Range, deg. F.
Ethyl alcohol	200 to 400	Aniline	400 to 700
Benzine	200 to 500	Sulphur dioxide	20 to 250
Water	200 to 600	Ether	100 to 300
Toluene	250 to 500	Methyl ether	−20 to 200

A vapor-pressure thermometer is not subject to error due to variation in temperature of the capillary if installed under conditions for which specified. The capillary may be of any length up to 200 ft. As a recording instrument it has the disadvantage of using a chart with a non-uniform scale which cannot be integrated with an ordinary planimeter. Also, its accuracy is affected by the elevation of the bulb above or below the Bourdon spring and by changes in barometric pressure. The error may amount to as much as would obtain between sea level conditions and elevations of 10,000 ft. and may range from 0.8% to 2.6%, depending on range of the thermometer, the part of the range that is used and the liquid in the instrument. The greatest error occurs with temperatures near the lower end of the range of the instrument. With a vapor-pressure thermometer,

temperature of the bulb usually must be above or below temperature at the spring or along the capillary.

GAS-FILLED THERMOMETERS chiefly utilize nitrogen as the working gas. The temperature range is −60° to 1000° F. The length of capillary that may be used is unlimited, and installations with capillaries several hundred feet long are not uncommon. Gas-filled thermometers are subject to errors if the capillary is at a different temperature in service than that at which it was calibrated.

3. PYROMETRY

The following division of pyrometric methods is given by Burgess (High Temperature Measurements): 1. The gas pyrometer, which utilizes the measurement of change of pressure of a constant volume of gas. See Bourdon Tube Thermometers, p. 3–09. 2. Calorimetric pyrometer, based on the elevation of temperature of a known volume of water by a mass of metal, at the temperature to be ascertained, dropped into the water. It is useful for intermittent researches in industrial establishments. Platinum is used in the laboratory, and nickel in the industrial plant. This method is practically obsolete (1935). 3. Radiation pyrometer, depending on the heat radiated by warm bodies. Its indications are influenced by the variable emissive power of the various substances. It is convenient for the determination of very high temperatures, as those of the electric arc, the sun, and very hot furnaces. It is useful for measuring the temperature of moving objects, as billets, etc., particularly when an automatic record is desired. 4. Optical pyrometer, using either the photometric measurement of radiation of a given wave length of a definite portion of the visible spectrum, or the disappearance of a bright filament against an incandescent background. It also is influenced, but to a lesser extent than radiation pyrometers, by variable emissivity. It is principally used in industry to determine temperature of bodies difficult of access, *i.e.*, liquid flowing metal, metal in a furnace, moving billets, etc. The optical pyrometer cannot be made recording. It is the best instrument for measuring temperatures above 3000° F. 5. Electrical resistance pyrometer, which utilizes variations in the electrical resistance of platinum or other metals with

temperature. It is correct up to 1800° F. but requires fragile and delicate parts. 6. Thermo-electric pyrometer, utilizing the electro-motive forces developed by the difference in temperature of two similar thermo-electric junctions opposed to one another. It is extensively used in industrial works for the measurement of temperatures up to 2700° F. 7. Contraction pyrometer (Wedgwood) which utilizes the permanent contraction taken by clayey materials when subject to more or less high temperatures. It is used only in a few pottery works. 8. Fusible cones, utilizing the unequal fusibility of earthenware cones of varied composition. These give only discontinuous indications. They are in general use in pottery works and similar industries.

The type of instrument to be used in any particular case depends on the temperature and on the conditions of operation. With thermo-electric pyrometers, the couple and its protecting tube must be chosen with regard to the temperature, the character of the gases present in the furnace and the time lag that is permissible. Table 6 will serve as a guide for the selection of the pyrometer suitable for different industrial conditions.

Pyrometers

RADIATION PYROMETER.—The intensity of the radiant energy emitted by a body is an indication of the temperature of that body. The intensity of radiation depends both upon the temperature of the body and upon the material composing it. If two similar hot bodies are at the same temperature, and the first is found to radiate energy at twice the rate of the second, the first is said to have twice the emissive power of the second. A material with the highest possible emissivity is known as a " black body." Black-body conditions are obtained by heating uniformly a hollow enclosure and measuring the radiation from a small opening in the walls. The numerical value 1 is usually applied to the emissivity of a black body and all other materials thus have an emissivity of less than 1. (See also Radiation, p. 3–31.)

In the radiation pyrometer the emissions from a radiant body are focused to fall upon the hot junction of a small thermocouple in the pyrometer, and the temperature to which this junction rises is approximately proportional to the rate at which the energy falls upon it. According to the Stefan-Boltzman law, this temperature is proportional to the 4th power of the absolute temperature of the source of radiation. The electro-motive force generated by this temperature rise is measured by a galvanometer or potentiometer, as in the thermo-electric pyrometer, which is calibrated to determine the relation between the electro-motive force so developed and the temperature of the radiant body. The energy waves radiating from the body are focused by a concave mirror upon the thermo-electric couple. Dust accumulations upon this mirror may reduce its reflection coefficient to such an extent that errors of 100° to 200° C. may be developed, and precautions should be taken to prevent dust entering the instrument. The readings generally are independent of the distance of the instrument from the source of radiation, providing that the image must more than cover the disc or black spot in the instrument, although this condition is not always realized. The radiation pyrometer tends to give a reading lower than the true reading as the sighting distance is increased or the size of the radiant body is decreased. It is, therefore, desirable to locate the instrument as closely as possible to the body whose temperature is to be measured.

Radiation pyrometers are calibrated to read correctly when sighted on a black body.

2190	3180	....	....	2300	2290

Most furnaces approximate black body conditions. Materials in the furnace, and at the same temperature, cannot be distinguished from the surroundings, and may be considered black bodies. If the coefficient of actual emissivity of the material is 0.45, its reflection coefficient will be 0.55, and the total emissivity of the body will be 1.0, or that of a black body. That is 55% of the energy radiated from the body will be reflected from the surrounding walls, which are at the same temperature. If, however, the material be removed from the furnace, it then will emit but 45% of the radiant energy of a black body at the same temperature.

Materials in the open, whose temperature is to be measured, therefore, should have a correction applied to the observed temperature to convert it to true temperatures. Table 7 shows true temperatures corresponding to apparent temperatures observed with a radiation pyrometer and sighted on materials in the open.

For details of construction of radiation pyrometers, consult catalogs of Thwing Instrument Co., Philadelphia; Brown Instrument Co., Philadelphia; Taylor Instrument Co., Rochester, N. Y.; Leeds & Northrup Co., Philadelphia.

Optical Pyrometer.—The optical pyrometer is similar to the radiation pyrometer in that it measures the energy radiated from incandescent bodies, but measures the light energy instead of the heat energy. A source of light of constant brightness in the pyrometer is compared with the luminosity of the body whose temperature is to be measured. In one type, the pyrometer is focused on the source of energy, and then wedges of absorbing glass are adjusted until the lights from the two sources appear of the same intensity upon the field of the instrument. A color screen causes the light to be monochromatic (usually red). A scale which reads directly in degrees of temperature, attached to the absorbing wedges, is calibrated to show the temperature corresponding to different positions of the wedges. Another type of optical pyrometer compares the brightness of the filament of an electric lamp in the pyrometer with the brightness of the body whose temperature is being measured. The current through the filament is adjusted, until the filament disappears when viewed against the radiant body. The instrument is so calibrated that the current required for the lamp is a direct reading of the temperature of the body in question.

Optical pyrometers are calibrated to read correctly when sighted on a black body. Objects in the furnace which are practically indistinguishable when heated, approximate black body conditions, and the temperature measurement is not seriously in error. Such error as exists will give a reading higher than the true reading, if the furnace walls are brighter than the material and lower than the true reading if the material is brighter than the walls. The pyrometer should be sighted through a small peep hole when approximate temperature uniformity is reached, or through a deep wedge-shaped cavity or hole in the material itself.

The optical pyrometer sighted on glowing material in the open reads too low. Corrections are necessary for materials whose temperature is measured under such conditions. Table 8 gives the corrections for various industrial materials sighted on in the open, when measured by optical pyrometers. The optical pyrometer will not give satisfactory readings when sighted through flames or smoke. The presence of flames will increase

the temperature readings, while smoke will cause the readings to be several hundred degrees low.

For details of the construction of optical pyrometers consult catalogs of Taylor Instrument Co., Rochester, N. Y.; Scientific Materials Co., Pittsburgh; Leeds & Northrup Co., Philadelphia; Shore Instrument Co., New York.

RESISTANCE PYROMETERS are made of platinum for temperatures up to about 1800° F., and of nickel for temperatures up to about 600° F. The variation in the electrical resistance of these metals with changes of temperature may be determined with a Wheatstone bridge or a galvanometer. These pyrometers are largely used for the measurement of low temperatures, and to some extent for high temperatures. They are of value in laboratory work for precision measurements. An important use is the accurate measurement of steam temperature. Resistance pyrometers are made for industrial use, and are applied to high temperatures where higher accuracy is desired than is possible with a base-metal thermocouple if the temperatures are not high enough to give the required sensitivity with a noble metal thermocouple. The thermocouple usually is preferred, due to its greater simplicity and lower first cost.

THERMO-ELECTRIC PYROMETERS.—The thermo-electric pyrometer consists essentially of a thermocouple of two different metals or alloys. The wires composing it are fused together at one end to form the measuring (hot) junction which is exposed to the temperature to be measured. The other ends, called the reference (cold) junction, are maintained at a constant temperature, as room temperature. The electro-motive force, induced by the difference in temperature between the two ends, is proportional to the temperature difference and may be measured by an indicating instrument, as the millivoltmeter or a potentiometer. These, together with lead wires connecting the reference junctions to the indicating instrument, complete the pyrometer.

The original thermo-electric pyrometer, as developed by Le Chatelier, employed a thermocouple consisting of one wire of platinum and one of an alloy of platinum 90%, and rhodium 10%. This couple may be used with temperatures up to about 2700° F. with an accuracy of about 5° F. Other combinations known as base metal couples are available and are of sufficient accuracy for industrial use. Up to 675° F. a copper-constantan couple may be used with extreme precision, or to within ±10° F. up to 900° F. Up to 1600° F. iron-constantan or nichrome-constantan couples may be used. Below 2000° F. alloys of chromium and nickel and of aluminum and nickel, known as chromel-alumel and nichrome-alumel, may be used in continuous service. For temperatures above 2700° F. the optical or radiation pyrometer should be used.

Thermo-electric pyrometers are calibrated for a certain reference junction temperature. Any variation in this temperature will vary the electro-motive forces in the couple, and therefore give a false indication of furnace temperature. If a thermo-electric couple is used at a different temperature than that for which it was calibrated, the true temperature of the measuring junction is $T + tK$, where T = observed temperature, t = difference between the temperature at which the reference junction was calibrated and the temperature at which it was used; K = a constant whose value is given in Table 9. These corrections may be read directly by setting the pointer of the galvanometer to read the reference junction temperature when the couple is disconnected. In the Bristol thermo-electric pyrometer a bi-metallic spring connected to one of the control springs of the moving coil performs this adjustment automatically. The reference junction must be located at the indicating instrument, or connected to it by compensating lead wires which will minimize reference junction errors. In Leeds & Northrup pyrometers, automatic compensation of reference junction is obtained by use of a nickel coil. For description see Pyrometry Symposium of A.I.M. & M.E., 1921, p. 206.

Compensating lead wires usually are of the same materials as those composing the couple. This, in effect, transfers the reference junction to the terminals of the indicating

instrument or to a point where the temperature is fairly constant. If the reference junctions be buried 10 ft. below ground, temperature will be constant to within 5° F. throughout the year. For platinum-rhodium couples, compensating leads of these materials are expensive. The Bristol Co. has developed lead wires consisting of copper and of a copper-nickel alloy for this type of couple, the copper being connected to the platinum-rhodium wire of the couple and the copper-nickel wire to the platinum wire. The reference junction is located at the indicator end of the compensating leads, which, while they do not compensate individually, taken together will compensate to within 9° F. for a variation of 360° F. in the lead couple-wire junction.

PROTECTION OF THERMOCOUPLES.—Thermocouples, especially the platinum-rhodium type, are sensitive to rough handling and should be protected if there is danger of their coming in contact with materials in the furnace. While the use of a protecting tube introduces a certain time lag in the reading of the instrument, this is unimportant unless instantaneous values of temperature are required. The following properties are desirable in thermocouple protecting tubes: Low porosity to gases; low volatility; ability to withstand high temperature and sudden changes in temperature; ability to withstand mechanical shocks and stresses; high rigidity or viscosity; ability to resist corrosion due to molten metals or furnace gases. If rapid changes of temperature are to be measured, high thermal conductivity is desirable, although low conductivity usually is required so that the flow of heat along the tube shall be as small as possible. Table 6 shows the type of thermocouple and protecting tube for different services.

For the properties of the various metals used in protecting tubes, see Technologic Paper No. 170, U. S. Bureau of Standards, p. 91.

TEMPERATURE RECORDERS.—A record of temperature in furnaces, baths, etc., frequently is of great importance in industry. This can be obtained with Bourdon tube thermometers, and with pyrometers in which change of temperature is indicated by a change in potential of an electric current, as thermo-electric, resistance and radiation pyrometers. In these instruments a pen or other marking device that traces a record of fluctuations in temperature on a chart moved at a uniform rate by any suitable means, is substituted for the indicating pointer. The type of chart depends on the type of instrument used, the class of service, the temperature range, and other considerations. Catalogs of makers should be consulted, and their advice sought before making a selection.

Temperature recorders are widely used for central control of furnaces, as in heat treating, where accurate maintenance of predetermined temperatures is essential. Some types of instrument will record the temperature of several sources of heat at one time. They also may be arranged with a system of colored signal lamps to call to the attention of the attendant any deviation of temperature beyond the prescribed limits.

TEMPERATURE CONTROL is closely allied with temperature recording. It is accomplished by a modification of temperature recorders, whereby fluctuation of temperature causes the mechanism to open or close an electric circuit which operates a relay. This relay, in turn, controls a heavier current that operates the necessary valves, switches, dampers, etc., to increase or diminish the heat supplied to the apparatus whose temperature is being controlled.

Other types of temperature controller utilize vapor pressure or compressed air for actuating valves, switches, dampers, etc., for varying the supply of heat. The Bristol Co. builds an instrument in which air pressure is varied upon two sides of a diaphragm through suitable mechanism attached to the indicating arm. This variation in pressure operates a pilot valve, which in turn controls air pressure to actuate the heat supply valve or switch. In the type of temperature controller built by the Fulton-Sylphon Co. the vapor pressure system is used. The capillary connected to the heat-sensitive bulb is attached at its other end to a sensitive bellows which expands or contracts with changes in vapor pressure. This expansion and contraction is utilized to operate pilot valves or other means of controlling the heat supply. For light work the bellows acts directly on the control valve.

In certain types of controllers, a temperature record is also made. Other types can be arranged to control temperature at predetermined times; for instance, to supply heat to lead baths a couple of hours before starting time in the morning, so that they will be at the proper temperature when the men arrive. They also are used to shut off the source of heat at a predetermined time, as when a material is to be subjected to a given temperature for a given length of time.

Temperature controllers are quite sensitive, and will control temperatures to within 1/2 deg. F. in a 250-deg. range, or to within 2° F. in a 1000-deg. range.

The applications and arrangement of these instruments are so numerous and varied that extended treatment of the subject is not possible here. Makers should be consulted in regard to the selection of the type of instrument and its application to a given service.

MEASUREMENT OF TEMPERATURE BY PHOTO-ELECTRIC TUBE.—(*Ind. & Engg. Chem.*, Dec., 1931). The photo-electric tube is sensitive to light from visible spectrum and the near infra red-rays. As the temperature of a body changes, its brightness also changes. Changes in light falling on the tube change the flow of current in it, and hence it can be used for both temperature measurement and temperature control. The current developed by the tube is amplified to operate control relays in the latter case. The tube is focussed on the image of the furnace wall or other surface to be measured, in the plane of a diaphragm in front of the tube which allows only the center portion of image to pass through. See Fig. 7. It is important that the tube always observes the same area of hot body. The apparatus is calibrated by determining the temperature of the furnace or body by means of pyrometer or otherwise, adjusting the variable diaphragm in the tube housing until the correct temperature is indicated on the scale of the tube. But one calibration is necessary, since for monochromatic radiation the logarithm of the energy radiated is proportional to the reciprocal of the temperature. This method of measuring temperature can be applied to high temperatures and to atmospheres deleterious to thermocouples or pyrometers.

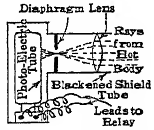

Fig. 7. Temperature Measurement b Photo-electric Tube

MEASUREMENT OF SURFACE TEMPERATURES (M. W. Boyer, J. Buss, F. W. Adams and R. H. Kean, *Ind. & Engg. Chem.*, July, Aug., 1926). A series of experiments showed the error in the measurement of surface temperatures by several different methods. The experiments were made on a steam chest cover ranging from 221° F. to 305° F. The methods used were: *A*. Thermometer under pad; *B*. Thermocouple under pad; *C*. Thermocouple of separate wires making contact through the metal surface itself; *D*. Thermocouple soldered to surface; *E*. Thermocouple embedded in surface; *F*. Compensated thermocouple held against surface. The following results were obtained:

Method	*A*	*B*	*C*	*D*		
Max. error, deg., C.	−17.8	−8.3	−8.3	−3.6		1.1
Min. error, deg., C.	−11.4	−5.8	−1.9	−2.7	−1.1	
Calculated error, %*	18	9	7	4	1	

* Based on heat loss by radiation and convection, as calculated, from body at 270° F. to room at 68° F.

The compensated couple is recommended for measurement of surface temperatures of either stationary or moving bodies. It consists of a means of applying sufficient heat to the exposed side of the thermocouple to prevent any heat loss through it. A bare couple had such large heat loss from the couple that it never attained the surface temperature. Fig. 8 diagrammatically represents the method of compensating. If the two couples show a difference of temperature, heat is flowing from the measuring to the regulating couple. In such event, heat is supplied by the heating coil until both couples show the same temperature. The temperature of either couple then is the temperature of the surface.

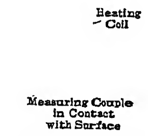

Fig. 8. Compensated Thermocouple

Pyrometric Cones

A pyrometric cone is a three-sided pyramid of mineral mixtures, the mixtures being so graded that they are affected by heat at different temperatures. A standard pyrometric cone, depending on its position in the series is either 3 in. high by $^5/_8$ in. wide at the base, or $^{25}/_{32}$ in. high by $^3/_8$ in. wide at the base. When heated under standard conditions, it bends at a definite known temperature. Pyrometric cones are used principally in clay, pottery and allied industries to determine the heat conditions of kilns, furnaces, etc. The softening or fusion is not altogether a matter of temperature, the element of time and character of surrounding gases also having an effect. Table 10 shows fusion points of pyrometric cones according to the original scale and according to the 1926 scale. The figures for the latter scale were obtained at the U. S. Bureau of Standards by Fairchild and Peters (*Jour.* Am. Ceramic Soc., vol. ix, p. 701, 1926).

4. TEMPERATURE DETERMINATION BY COLOR

COLOR-TEMPERATURE SCALES.—The statement that the experienced eye unaided can judge the temperature of a body by its color should be accepted with caution. Skilled observers may vary 100° F. or more in their estimation of relatively low temperatures by color, and beyond 2200° F. it is practically impossible to make estimations with any certainty whatever. (Bull. No. 2, U. S. Bureau of Standards, 1905.) This

statement is borne out by Table 11, which presents three widely-used color-temperature scales, formulated by H. M. Howe, F. W. Taylor and The Halcomb Steel Co., respectively. It will be observed that there is a variation of 360° F. in the temperature ascribed to cherry red, and similar discrepancies throughout the scales. Temperature determinations by color are unreliable and should be used only for the crudest class of work.

Temper Colors and Temperatures.—The Halcomb Steel Co. (1908) gives the following heats and temper colors of steel:

Deg. C.	Deg. F.	Colors	Deg. C.	Deg. F.	Colors	Deg. C.	Deg. F.	Colors
221.1	430	Very pale yellow.	254.4	490	Yellow-brown.	282.2	540	Full purple.
226.7	440	Light yellow.	260.0	500	Brown-yellow.	287.8	550	Dark purple.
232.2	450	Pale straw-yellow.	265.6	510	Spotted red-brown.	293.3	560	Full blue.
237.8	460	Straw-yellow.	271.1	520	Brown-purple.	298.9	570	Dark blue.
243.3	470	Deep straw-yellow.	276.7	530	Light purple.	315.6	600	Very dark blue.
248.9	480	Dark yellow.						

5. ABSOLUTE TEMPERATURE—ABSOLUTE ZERO

The absolute zero of a gas is a theoretical consequence of the law of expansion by heat, assuming that it is possible to continue the cooling of a perfect gas until its volume is diminished to nothing.

The volume of a perfect gas increases $^1/_{273.1}$ of its volume at 0° C. for every increase of temperature of 1° C., and decreases $^1/_{273.1}$ of its volume at 0° C. for every decrease of temperature of 1° C. At −273.1° C. the volume would then be reduced to nothing. This point, −273.1° C. = − 459.6° F., or 491.6° F. below the temperature of melting ice, is called the absolute zero, and absolute temperatures are measured on either the Centigrade or the Fahrenheit scale, from this zero. The freezing-point, 32° F., corresponds to 491.6° F., absolute. If p_0 = pressure, and v_0 = volume of a perfect gas at 32° F. = 491.6° absolute, $= T_0$, and p = pressure and v = volume of the same weight of gas at any other absolute temperature T, then

$$\frac{pv}{p_0 v_0} = \frac{T}{T_0} = \frac{t + 459.6}{491.6}; \quad \frac{pv}{T} = \frac{\quad}{T_0} \quad R.$$

. cubic foot of dry air at 32° F. at the sea level (barometer 29.921 in. of mercury) weighs 0.080728 lb. The volume of one pound is 1/0.080728 = 12.387 cu. ft. The pressure is 2116.3 lb. per sq. ft.

$$R = \frac{p_0 v_0}{T_0} = \frac{2116.3 \times 12.387}{491.6} = \frac{26{,}214}{491.6} = 53.32.$$

QUANTITATIVE MEASUREMENT OF HEAT

; **OF HEAT.**—Several units for measuring the quantity of heat in a body are in use. The relations between them are given in Table 1.

The British Thermal Unit (B.t.u.) generally used in engineering work in the United States and Great Britain is $^1/_{180}$ of the heat required to raise the temperature of 1 lb. of water from 32° F. to 212° F. It formerly was defined as the quantity of heat required to raise 1 lb. of water from 62° to 63° F., but the former definition is now generally accepted.

The Kilogram-calorie or large calorie (kg.-cal.) is the heat required to raise the temperature of 1 kilogram of water from 14.5° to 15.5° C., or $^1/_{100}$ of the heat required to raise 1 kilogram of water from 0° C. to 100° C.

The Gram-calorie, small calorie, or 15° calorie (gm.-cal.), generally used in scientific work, is the heat required to raise 1 gram of water from 14.5° to 15.5° C.

The Mean Calorie (Mean cal.) is $^1/_{100}$ of the heat required to raise the temperature of

* Exact value, by definition. † 1 absolute joule = 10 ergs. ‡ Mean value.

1 gram of water from 0° to 100° C., the latent heats of fusion and boiling not being considered.

The Ostwald Calorie (Ost. cal.), frequently used in electro-chemistry, is the heat required to raise the temperature of 1 gram of water from 0° to 100° C.

The Pound Calorie (lb.-cal.) is the heat required to raise the temperature of 1 lb. of water 1° C.

The Mechanical Equivalent of Heat is the number of foot-pounds of mechanical energy equivalent to one British thermal unit, heat and mechanical energy being mutually convertible. The U. S. Bureau of Standards has determined that 1 B.t.u. = 778.57 ft.-lb., which is 1/180 of the change in total heat along the saturated liquid water line from 32° to 212° F. Table 2 gives the mechanical equivalent of heat as expressed in various units.

SPECIFIC HEAT

THERMAL CAPACITY.—The thermal capacity of a body between two temperatures T_0 and T_1 is the quantity of heat required to raise the temperature from T_0 to T_1.

SPECIFIC HEAT.—The specific heat of any substance is the ratio of the heat required to raise the temperature of a unit weight of that substance 1 deg. and the quantity of heat required to raise the temperature of the same weight of water 1 deg., usually from 62° to 63° F.

* Dr.-Ing. P. Oberhoffer, in *Zeit.* des Vereines Deutscher Ingenieure (*Eng. Digest*, Sept., 1908), describes some experiments on the specific heat of nearly pure iron. The following mean specific heats were obtained:

Temp., deg. F.	500	600	800	1000	1200	1300
Specific Heat	0.1228	0.1266	0.1324	0.1388	0.1462	0.1601
Temp., deg. F.	1500	1800	2100	2400	2700	
Specific Heat	0.1698	0.1682	0.1667	0.1662	0.1666	

The specific heat increases steadily between 500° and 1200° F. Then it increases rapidly to 1400° F., after which it remains nearly constant.

DETERMINATION OF SPECIFIC HEAT.—A hot body of known weight and temperature, immersed in a mass of liquid of known specific heat, weight and temperature, will raise the temperature of the liquid until both liquid and body are at the same temperature. If C_1 and C_2 = specific heat; w_1 and w_2 = weight; t_1 and t_2 = temperature, of the hot body and the liquid respectively; and if T = final temperature of both, then, $C_1 = C_2w_2(T - t_1) \div w_1(t_1 - T)$.

Another method consists in determining the amount of electrical energy required to raise the temperature of a unit weight of the substance 1 deg. in 1 min., converting the result into heat units on the basis of 1 watt = 0.05685 B.t.u. per min.

SPECIFIC HEATS OF VARIOUS SUBSTANCES.—The specific heats of the chemical elements and of the more commonly-used gases, liquids and solids of engineering are given in Tables 1 to 6. Except where otherwise noted, these tables are based upon the physical tables published by the Smithsonian Institution.

The specific heat of many substances varies with temperature and probably is greater when the substance is liquid than when solid. In a number of cases the specific heat at

CHANGE OF STATE—LATENT HEAT

LATENT HEAT is the quantity of heat required to change the state, as solid or liquid, of a body without rise of temperature.

Latent Heat of Fusion is the quantity of heat required, at the fusion temperature, to change a body from the solid to the liquid state, without change of temperature. When the body changes from the liquid to the solid state this same amount of heat is rejected to the atmosphere or other surrounding bodies. See Tables 7 and 8 for latent heats of various materials.

Latent Heat of Vaporization is the quantity of heat required to change a liquid, at the boiling point, to a vapor under constant pressure, without change of temperature. When the substance is changed from the vapor to the liquid state, under the same conditions of temperature and pressure, this same quantity of heat will be rejected from the substance. See Table 8 for latent heats of vaporization of various substances.

TOTAL HEAT OF EVAPORATION (ENTHALPY) is the sum of the heat which disappears in evaporating one pound of a given substance at a given temperature (or latent

EXPANSION BY HEAT

EXPANSION OF AIR.—In the Centigrade scale the coefficient of expansion of air per degree is 0.003665 = $^1/_{273}$; that is, the pressure being constant, the volume of a perfect gas increases $^1/_{273}$ of its volume at 0° C. for every increase in temperature of 1°. In

INVAR, an alloy of iron with 36% Ni, has a smaller coefficient of expansion with the ordinary atmospheric changes of temperature than any other metal or alloy known. This alloy, sold under the name of Invar, is used for scientific instruments, pendulums of clocks, steel tape-measures for accurate survey work, etc. The Bureau of Standards found its coefficient of expansion to range from 0.000000374 to 0.000000440 for 1° C., or about $^1/_{28}$ of that of steel. For all surveys except in the most precise geodetic work a tape of invar may be used without correction for temperature. (*Eng. News*, Aug. 13, 1908.)

PLATINITE, an alloy of iron with 42% Ni, has the same coefficient of expansion and contraction at atmospheric temperatures as has glass. It can, therefore, be used for the manufacture of armored glass, that is, a plate of glass into which a network of steel wire has been rolled, and which is used for fireproofing, etc. It also can be used instead of platinum for the electric connections passing through the glass plugs in the base of incandescent electric lights. (Stoughton's Metallurgy of Steel.)

HEAT TRANSMISSION

By W. J. King

References. Heat Transmission, by W. H. McAdams, McGraw-Hill, N. Y., 1933. The Calculation of Heat Transmission, by M. Fishenden and O. A. Saunders, H. M. Stationery Office, London, 1932. The Basic Laws and Data of Heat Transmission, by W. J. King, *Mech. Engg.*, March-Aug. inclusive, 1932.

THE FUNDAMENTAL HEAT TRANSFER PROCESSES are Conduction, Convection and Radiation. Evaporation and Condensation are special forms or combinations of conduction and convection.

Conduction is the transmission of heat by molecular vibration from one part of a body to another or from one body to another body in direct contact with it.

Convection is the transfer of heat between a fluid and a surface by the circulation or mixing of the fluid. In free or natural convection the fluid motion is caused by gravity forces due to difference in density between the hotter and cooler parts; in forced convection the motion is produced artificially, as by a pump, blower, or other external forces not connected with the temperature of the fluid.

Radiation is the transmission of heat in the form of radiant energy or wave motion in the ether, from one body to another across an intervening space. This term sometimes is loosely used to denote dissipation of heat from the outer surface of a furnace or pipe, which usually includes both radiation and convection.

Heat may be transmitted by any one of the three processes acting alone, or by combinations acting in series or in parallel, as in the case of most practical applications. Although it is sometimes convenient to deal only with the combined or overall heat transfer, as from one fluid to another across a dividing wall, this sort of treatment does not bring out the effects of the individual components, and the data are not of such general utility as when these components are treated separately. The present section is therefore devoted to the basic individual processes listed above. Whenever the total or overall heat transmission is desired, care should be taken to include all of the processes acting in conjunction, as shown in the section on Heat Transfer Applications on page 3-34.

1. CONDUCTION

CONDUCTIVITY.—In conduction problems, the fundamental unit is the *thermal conductivity* K, which is a specific property of a substance. In engineering units, conductivity is defined as the rate of heat flow in B.t.u. per hour through a cross-sectional area of 1 sq. ft. for a temperature difference of 1 deg. F. across a thickness or length of 1 in. in the direction of the heat flow. In any case, if q = heat flow, B.t.u. per hr.; A = area,

Table 1.—Conversion Factors for K

Unit of Heat	Unit of Time	Unit of Area	Unit of Temperature Diff.	Unit of Thickness	Divide K by
B.t.u.	hour	sq. ft.	deg. F.	inch	1
B.t.u.	hour	sq. ft.	deg. F.	foot	12
Gram-calorie	second	sq. cm.	deg. C.	cm.	2903
Kg.-calorie	hour	sq. meter	deg. C.	meter	8.064
Watt-seconds	second	sq. cm.	deg. C.	cm.	694
Kw.-hr.	hour	sq. ft.	deg. F.	inch	3415

sq. ft.; L = thickness, in.; = temperature at hot end of path; t_2 = temperature at cold end, deg. F., then

$K = \cdot$

L

Factors for obtaining values of K in various other common units are given in Table 1.

In the case of radial flow through a thick-walled cylinder, A should be taken as the logarithmic mean of the outer and inner areas; $A = (A_2 - A_1)/\log_e (A_2/A_1)$.

It is sometimes convenient to obtain a heat transfer coefficient h in B.t.u. per hr. per sq. ft. per deg. F., for a given thickness of a solid material, such as the metal wall of a pipe. This is done by dividing the conductivity by the thickness, $h = K/L$ . . . . . [3].

Conductivity of Gases

THE THERMAL CONDUCTIVITY OF ANY GAS may be calculated with fair accuracy by the formula

$$K = bZc_v \qquad [4]$$

where K = B.t.u. per hr. per sq. ft. per deg. F. per in.; Z = viscosity in centipoises; c_v = specific heat at constant volume; b = a constant depending on the number of atoms in the molecule as follows: monatomic gases, $b = 71$; diatomic gases, $b = 55.2$; triatomic gases, $b = 49.4$; complex gases, $b = 38$. For all gases K increases with the temperature, but is practically independent of the pressure, except at very low or high pressures. This formula is based on the kinetic theory and has been verified experimentally.

If the values of K in Table 2 are used to compute the heat flow across a gas layer, it must be remembered that a considerable amount of heat also may be transferred by convection and radiation as parallel processes.

The Conductivity of Air at any temperature T, deg. F. absolute, may be obtained from the formula

$$K = (0.01 + 1.076 \times 10^{-6}T)\sqrt{T}/(1 + 211/T) \qquad [5]$$

Conductivity of Liquids and Solutions

The following empirical formula is given by J. F. Dowine-Smith (*Ind. and Engg. Chem.*, vol. xxii, 1930, p. 1246) for the value of K for pure liquids

$$K = 2.35S^{2.15}C^{1.55}M^{0.192}/Z^{0.12} \qquad [6]$$

where S = specific gravity; C = specific heat; M = molecular weight; Z = viscosity, centipoises.

The conductivity of most organic liquids decreases slightly with increasing temperature. For water, K increases to a maximum at 270° F., and then decreases until its value at 570° F. is the same as at 40° F. The conductivity of aqueous solutions generally is lower than that of water by an amount roughly proportional to the concentration of the solute.

Conductivity of Metals and Alloys

According to the Weidemann-Franz-Lorenz Law (See *Jour.* Inst. of Metals, vol. xxxix, 1928, p. 337) the thermal conductivity K, B.t.u. per hr. per sq. ft. per deg. F. per inch, of any metal or alloy can be obtained from the relation $K\omega = 58\ T$, where ω = electrical resistivity, ohms per circular-mil-ft.; T = temperature in deg. F., absolute. Except

Table 2.—Thermal Conductivity, K, of Gases

(In B.t.u. per hr. per sq. ft. per inch thickness per deg. F. difference in temperature)

Gas	Temperature, deg. F.	K	Gas	Temperature, deg. F.	K
Air	32	0.163	Hydrogen	32	1.130
"	212	0.211	"	212	1.435
Ammonia	32	0.141	Methane	32	0.210
"	212	0.206	Neon	32	0.031
Argon	32	0.110	Nitrogen	32	0.163
Carbon dioxide	32	0.097	"	212	0.210
" "	212	0.133	Nitrous oxide	32	0.100

Chlorine	32	0.053	Oxygen	32	0.165
Ethane	32	0.126	"	212	0.215
Ethylene	32	0.114	Steam	212	0.162
Helium	32	0.970	"	572	0.254
			Sulphur dioxide	32	0.056

at very low temperatures, this relation has been found to hold fairly closely for pure metals and approximately for alloys. For pure metals any variation of conductivity with temperature generally is small, although in some cases there is an appreciable decrease at higher temperatures. For most alloys, the value of K increases, and for the ferrous metals it decreases with rising temperatures.

The addition of a small amount of another metal, or an impurity, usually will result in a sharp drop in conductivity of a pure metal, particularly when a solid solution is formed. Practically all of the alloy steels have lower conductivities than wrought iron. When the percentage of added constituents (C, Co, Cr, Mn, Mo, Ni, Si, V, W, etc.) is small, the value of K usually is around 280, with lower values as the percentage increases.

MISCELLANEOUS SOLID MATERIALS.—In general the conductivities of non-metallic solid materials increase very considerably with density, temperature, and moisture

2. CONVECTION

Free or Natural Convection

Cases treated under this heading are for the conditions of still air or a body immersed in an unagitated fluid. Coefficients refer only to the convection component of the total heat transfer, and do not include radiation, which, in the case of gases, generally should be computed separately as an additional component.

THE CONVECTION COEFFICIENT h, sometimes called the *film coefficient*, is expressed in B.t.u. per hr. per sq. ft. of surface per deg. difference in temperature between the surface and the main body of the fluid. In free convection, the value of the coefficient h is affected very little by the nature of the surface, but depends principally upon the size, temperature difference and physical properties of the fluid.

Free Convection in Air.—For vertical plane surfaces in air,

$$h = 0.30(\theta/L)^{1/4} \qquad [7]$$

where h = convection coefficient, B.t.u. per hr. per sq. ft. per deg. F.; θ = temperature difference, deg. F.; L = height, ft. The convection from a horizontal surface facing upward is about 30% greater, and facing downward 30% less, than in the vertical position.

The convection coefficient for horizontal or vertical pipes in air is given by

$$h = 0.42(\theta/d)^{1/4} \qquad [8]$$

where d = pipe diameter, in., other notation being as before.

Free Convection in Liquids.—In this case the convection coefficient represents the total heat transfer, since radiation is not involved. Ordinarily, the effects of the shape or size of the body are not significant, except that for fine wires the coefficients will be considerably higher than those given below.

Convection in Water.—For bodies of ordinary size in water

$$h = 0.165(t_w + 30)\sqrt{\theta} \qquad [9]$$

where t_w = water temperature deg. F., other notations being as before. This formula does not apply when the surface temperature is above the boiling point. Values of h for various values of t_w and θ are given in Table 6.

Table 6.—Heat Transfer Cofficients for Surfaces in Unagitated Water

B.t.u. per hr. per sq. ft. per deg. F.

Water Temperature, t_w, deg. F.	Temperature Difference θ, deg. F.									
	10	20	30	40	50	60	70	80	90	100

160	99	140	172	198	222	....	....	....	....	....
180	110	155	190	....	....	....	....	....	....	....

Convection in Oils.—If Z = viscosity in centipoises at the average of the surface and oil temperatures, the convection coefficient may be obtained from $h = 17\theta^{1/4}/Z^{0.4}$ . . . . [10].

Forced Convection

When the fluid is circulated artificially over the heat transfer surface, the value of the coefficient h is governed by the velocity and physical properties of the fluid, and by the size, shape, arrangement and nature of the surface. In general, roughening the surface, or anything that promotes turbulence in the fluid flow, will increase the heat transfer coefficient. In liquids, the convection coefficient represents the total heat exchange. This also generally is true of gases, as regards the exchange of heat between the surface and the gas, but with exposed surfaces the additional effect of radiation to or from the surroundings may be relatively significant, particularly at low velocities and high temperatures. The effect of humidity generally is negligible, except when the temperature of the surface is below the dew-point of the gas. Condensation then will occur as an additional process, governed by the vapor pressure difference.

Gas Film Coefficients

In the following formulas, which represent the best available data from various sources, h = convection coefficient, B.t.u. per hr. per sq. ft. per deg. F. temperature difference; v = gas velocity, ft. per sec.; G = mass velocity, lb. per sec. per sq. ft. of cross-sectional area = (linear velocity $v \times$ density, lb. per cu. ft.); c_p = specific heat at constant pressure; Z = viscosity, centipoises; t = average gas temperature, deg. F.; d = pipe diam., in.

For any gas flowing inside a tube, $h = 36\, c_p\, G^{0.8}(Z/d)^{0.2}$. . . . . [11]

For air flowing at right-angles across a single rod or pipe,

$$h = 8.2\, G^{0.58}(1 + 0.000576\, t)/d^{0.42} \quad [12]$$

In Tube Banks, the coefficient increases with the number of rows, and is somewhat higher when the tubes are staggered than when they are arranged in line with the flow. **For air flowing across staggered tubes 4 or more rows deep,**

$$h^* = \{1.7(t + 460)^{0.3}\, G^{2/3}\}/d^{1/3} \quad [13]$$

For smooth plane surfaces in ordinary atmospheric air at velocities $v < 15$ ft. per sec.,

$$h = 0.8 + 0.22\, v \quad [14]$$

At higher velocities,

$$h = 0.56\, v^{3/4}. \quad [15]$$

Coefficients for rough surfaces such as brick, concrete and stucco are from 20 to 50% higher than for smooth surfaces.

The curves, Fig. 1, give coefficients for air at atmospheric pressures and temperatures in the vicinity of 100 deg. F. For other conditions, equivalent velocity * may be obtained from the expression $v = 14.3\, G$, where G = mass velocity, lb. per sec. per sq. ft. of flow area. The formulas and curves for air also may be used for similar gases such as N_2, O_2 and CO; in case of flue gases the value of h usually is about 25% higher. Curves marked Cross Flow are representative of the data for finned tubing, although the latter vary considerably with size and spacing of fins, etc. Table 7 shows the effect of tube diameter upon the above coefficients.

Liquid Film Coefficients

LIQUIDS FLOWING IN PIPES.—For the heating of liquids in *turbulent flow* in pipes, Sherwood and Petrie (*Ind. and Engg. Chem.*, vol. xxiv, 1932, p. 736) give an equation which may be reduced to the form

$$h = 4.37 K^{0.6}\, G^{0.8}\, c^{0.4}/d^{0.2}\, Z^{0.4}. \quad [16]$$

where h = heat transfer coefficient, B.t.u. per hr. per sq. ft. per deg. F. difference between the pipe and liquid temperatures; K = thermal conductivity of the liquid, B.t.u. per hr. per sq. ft. per deg. F. per in.; G = mass velocity, lb. per sq. ft. per sec. = (linear velocity, ft.

Table 7.—Effect of Tube Diameter upon Forced Convection Coefficients

Dia	0.1	0.25	0.5	0.75	1	1.5			
	Multiply coefficient for 1-in. tube by								
Flow Inside Tube	1.59	1.32	1.15	1.06	1.0	0.92	0.87	0.76	0.66
Cross Flow, Single Tube	2.60	1.77	1.33	1.13	1.0	0.84	0.75	0.56	0.42
Tube banks	2.15	1.58	1.25	1.10	1.0	0.87	0.79	0.63	0.50

* In the case of tube banks the value of G or v should be taken as the maximum velocity between the tubes, *i.e.*, referred to the minimum free area rather than the face area of the bank.

Table 8.—Heat Transfer Coefficients for Water Flowing in a 1-in. Pipe

B.t.u. per hr. per sq. ft. per deg. F.

140	248	432	750	1040	1310	1570	1815	2280	2720
160	269	468	815	1130	1420	1700	1965	2470	2940
180	290	504	876	1215	1530	1830	2120	2660	3170
200	311	540	9[illegible]0	1300	1635	1960	2270	2850	3400

per sec. × density, lb. per cu. ft.); c = specific heat; d = inside diameter of tube, in.; Z = viscosity of liquid, centipoises. Fluid properties were taken at the average temperature of the main body of the liquid. This formula represents tests on water, acetone, benzine, kerosene and n-butyl alcohol. It is in good agreement with the results of other investigators and should be applicable to any fluid. Table 8 gives values of h for water flowing in a clean 1-in. pipe; for other pipe diameters multiply h by factors in Table 7.

Corrosion, Scale or Dirt on the pipe surface will reduce the coefficient considerably, in extreme cases by as much as 50%. Effect of pipe length generally is negligible when length > 20 diameters; for shorter pipes the coefficient may be appreciably higher.

COEFFICIENTS FOR COOLING.—When the fluid properties do not vary very widely over the temperature range, formula [16] will apply to cooling as well as to heating of liquids. With petroleum oils, however, the variation of viscosity is so rapid that it is difficult to obtain a formula that is valid for all conditions. Most of the data on heating of oils in turbulent flow are represented with reasonable accuracy by

$$h = 70\, v/Z^{0.63} \quad . \quad . \quad . \quad . \quad . \quad [17]$$

where v = linear velocity, ft. per sec.; Z = viscosity, centipoises, at the average of inlet and outlet temperatures. If the oil is being cooled, the coefficient is usually about 25% lower.

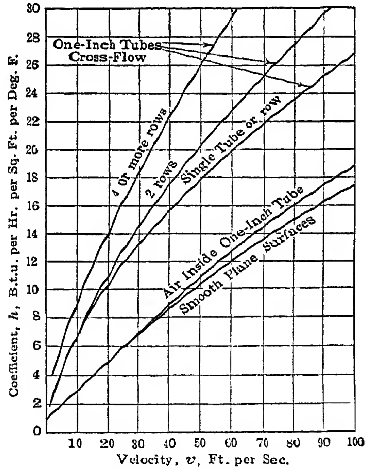
STREAMLINE OR VISCOUS FLOW.—For the heating of any liquid in streamline or viscous flow in pipes, the approximate value of the coefficient may be obtained from

$$h = 15\,(GcK^2/dL)^{1/3} \quad . \quad . \quad . \quad . \quad . \quad [18]$$

or for petroleum oils,

$$h = 43\,(v/dL)^{1/3} \quad . \quad . \quad . \quad . \quad . \quad . \quad [19]$$

where L = heated length of pipe, ft., and coefficient h is based on the arithmetic mean temperature difference between pipe and liquid, other notation being as before. A few data indicate that when the oil is being cooled the coefficient will be roughly 30% lower.



. 1. Coefficient of Heat Transfer for Air at Atmospheric Pressure and Moderate Temperature

FLOW IN CHANNELS OR ANNULAR SPACES.—For fluids flowing in channels or annular spaces it is customary to take d as the hydraulic diameter (4 × cross-sectional area ÷ perimeter), or, with concentric pipes, as the difference between the diameters.

3. RADIATION OF HEAT

Radiant energy may be regarded as a form of wave motion in the ether, which is manifested in various forms, as radio waves, light, heat and x-rays, depending upon the wave lengths. In the range of short wave lengths, known as the visible spectrum, radiant heat and light are identical physically. In the longer wave lengths, which are associated with lower temperatures, the radiation is invisible but it still follows the general laws of optics as regards propagation and reflection; *i.e.*, it travels in straight lines with the speed

of light, the intensity at any point varies inversely as the square of the distance from the source, and for a polished surface the angle of reflection is equal to the angle of incidence. On the other hand, it is important to note that this long-wave radiation from sources at temperatures below incandescence may be emitted, absorbed, reflected or transmitted to a very different degree than in the case of short waves from luminous sources. For example, ordinary window glass will transmit about 90% of the solar radiation falling upon it, but will almost completely absorb radiation from a source at a temperature below 1000° F. Also, at ordinary temperature, a white surface may be as good a radiator or absorber as a black one, whereas absorption of solar radiation increases with the darkness of the color.

DEFINITIONS.—**A Black Body** is a body that absorbs all the radiant energy falling upon it. Such a body also radiates energy at the maximum rate possible by virtue of its temperature.

The Emissivity of a body is the ratio of its radiating power to that of a black body.

The Absorptivity of a body is the fraction of the radiant energy falling upon it that is absorbed.

The Reflectivity of a body is the fraction of the radiant energy falling upon it that is reflected.

THE STEFAN-BOLTZMANN LAW, which has been verified experimentally, states that the total radiation from a black body is proportional to the fourth power of its absolute temperature. This may be expressed in the form

$$q = 0.174 \times 10^{-8} A T^4 \qquad [20]$$

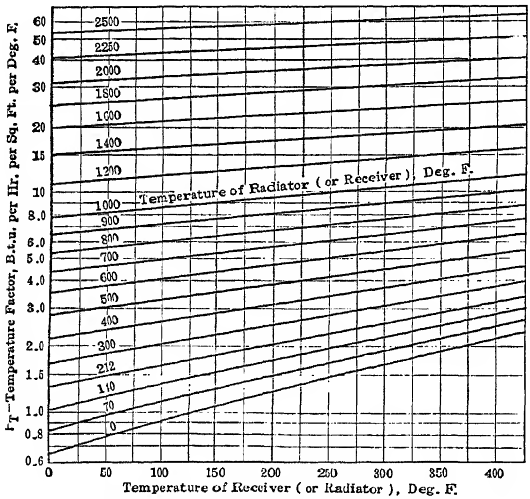


FIG. 2. Values of F_T (Multiply F_T by emissivity factor e' to obtain radiant heat transfer coefficient h_r)

where q = total radiation, B.t.u. per hr.; A = area, sq. ft.; T = absolute temperature, deg. F. For ordinary non-black bodies emissivity e represents the fraction of this amount of heat actually radiated, so that

Values of e are given in Tables 9 and 10. These expressions represent only the emission from a radiating body, and do not take into account the simultaneous absorption from the surroundings. What usually is desired in practical applications is the net exchange of radiation between a body and its surroundings, or between two bodies. In general, this depends, in a rather complex way, upon the solid geometry of the case (see H. C. Hottel, *Mech. Engg.*, vol. lii, 1930, p. 699), but for certain simple cases it can be calculated by convenient formulas.

In the following cases the net radiation is

$$q/A = 0.174\, e' \left[(T_1/100)^4 - (T_2/100)^4 \right] \text{ B.t.u. per hr. per sq. ft.} \qquad [21]$$

where T_1 = the higher, and T_2 = the lower absolute temperature, and e' = emissivity factor. It frequently is convenient to express this in the form of a radiant heat transfer coefficient, h_r, by dividing by the temperature difference. Thus, let F_T be the **temperature factor** defined by the expression

$$F_T =$$

The coefficient is then $h_r = e'F_T$ B.t.u. per hr. per sq. ft. per deg. F. Values of F_T for ordinary Fahrenheit temperatures are given in Fig. 2.

Case 1.—Radiation or absorption by a relatively small body in an enclosure. In this case $e' = e$, the emissivity of the body. As the size of the body approaches that of the enclosure, the emissivity factor approaches the value given for Case 2.

Case 2.—Two parallel planes whose areas are large compared to their distance apart. This involves the emissivities e_1 and e_2, of both surfaces, and

$$e' = 1/[(1/e_1) + (1/e_2) - 1] \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; [23]$$

Case 3.—Concentric cylinders or spheres. If the heat transfer rate is referred to the area A_1 of the enclosed body, then

$$e' = \frac{1}{\text{[illegible]}} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; [24]$$

Radiation in Gases and Flames.—In general, radiation or absorption by dry air, oxygen, nitrogen or hydrogen is inappreciable. In the case of carbon dioxide or water vapor the effect may be considerable, particularly for thick gas layers, high concentrations and high temperatures. For the calculation of radiation from gases and flames, see Haslam and Hottel, *Trans.* A.S.M.E. FSP-50-3, 1928, and Wilson, Lobo and Hottel, *Ind. and Engg. Chem.*, vol. 24, 1932, p. 486.

Emissivity and Absorptivity

KIRCHHOFF'S LAW states that the emissivity of any body is equal to its absorptivity for the same kind of radiation, *i.e.*, the same wave lengths. For practical purposes this law may be approximated by the statement that the absorptivity of any material is equal to its emissivity when the radiation is invisible. It should be noted, however, that a material or surface may have a low absorptivity for solar radiation and yet have a high emissivity at ordinary temperatures, as in the case of white paint.

EMISSIVITY OF METALLIC SURFACES.—The emissivity of a metallic surface depends to a marked extent upon the degree of oxidation. Values of e for bright metal surfaces are given in Table 9. The figures given in Table 10 show the normal variation of e for moderately to badly oxidized surfaces. For slightly oxidized or tarnished surfaces values of e intermediate between those of Table 9 and Table 10 should be used.

Table 9.—Emissivity e of Polished Metal Surfaces

Metal	Temperature		
	70° F.	1000° F.	3000° F.*
Aluminum	0.05	0.075	......
Brass	0.05	0.06	......
Copper	0.04	0.08	0.15
Gold	0.03	0.05	......
Iron, cast or wrought	0.20	0.25	0.28
Lead	0.08	......	......
Monel metal	0.07	0.10	......
Nickel	0.06	0.10	......
Platinum	0.036	0.10	0.20
Silver	0.025	0.035	......
Steel	0.20	0.25	0.28
Tin	0.08	......	......
Tungsten	0.03	0.09	0.25
Zinc	0.10	......	......

* Or molten, if melting point is below 3000° F.

Table 10.—Emissivity e of Oxidized Metals at Temperatures below 1500° F.

Metal	e	Metal	e
Aluminum	0.10–0.20	Iron and steel	0.60–0.90
Brass	0.25–0.60	Monel metal	0.40–0.50
Copper	0.55–0.75	Nickel	0.40–0.60

The Emissivity of Aluminum or Bronze Paints varies from 0.3 to 0.6, depending on age and amount of lacquer.

EMISSIVITY OF NON-METALLIC MATERIALS.—A careful study of the results of tests on several hundred different materials reported by about 30 investigators indicates that practically all non-metallic materials, such as porcelain, glass, rubber, paper, cloth, refractories, building materials, enamels and paints *of any finish or color* have emissivities between 0.85 and 0.95. In view of the lack of agreement in many cases, a value of $e = 0.9$ is recommended for all such materials.

SOLAR RADIATION.—On a clear day, the average solar radiation at noon upon a surface facing the sun is about $q = 320$ B.t.u. per hr. per sq. ft. Of this, the amount absorbed will be equal to aq, if a = absorptivity of the surface. For solar radiation the value of a depends primarily on the color, although it is influenced somewhat by the nature

and roughness of the surface. Approximate values of a for a few substances are given in Table 11.

Table 11.—Absorptivity a of Various Surfaces for Solar Radiation

Surface	a	Surface	a
Aluminum paint	0.35	Red brick or tile	0.65
Copper, polished	0.50	Silver, polished	0.07
Galvanized iron, new	0.65	Slate, gray	0.90
Lampblack	0.97	Steel, polished	0.45
Magnesium carbonate	0.02	White paper	0.25
Nickel, polished	0.40	Whitewash	0.25

4. HEAT TRANSFER TO BOILING LIQUIDS

Heat transfer coefficients from metal surfaces to boiling liquids are subject to extremely wide variations, depending chiefly on the nature of the surface, temperature difference, and nature and temperature of the liquid. Typical results obtained by various observers are given in Fig. 3. The value of h is affected so greatly by such factors as the amount of air dissolved in the liquid, the design of the apparatus and the presence of scale on the surfaces that it is not possible to obtain an adequate general correlation of the data.

Cryder and Gilliland (*Refrig. Engg.*, Feb. 1933, p. 78) give the results of tests on eleven different liquids, boiling at atmospheric pressure and heated by a horizontal brass cylinder 1 in. diameter, which are represented by the formula

$$h = 0.0617\theta^{2.4} K^{1.8} C^{0.4} S^{2.4}/Z^{3.2}, \qquad [25]$$

where h = heat transfer coefficient, B.t.u. per hr. per sq. ft. per deg. F.; θ = temperature difference, deg. F.; K = thermal conductivity of the liquid, B.t.u. per hr. per sq. ft. per deg. F. per 1 in.; C = specific heat; S = specific gravity; Z = viscosity, centipoises. This formula is of value mainly in indicating effects of temperature difference and fluid properties, as the constant term will vary with the type of heating surface. In boilers and evaporators values of h usually range from 400 to 2000 for water and from 50 to 500 for refrigerants and organic liquids, the higher values being associated with high heating rates.

5. CONDENSATION OF VAPORS

PURE VAPORS.—The following formulas, due to Nusselt, are in good agreement with the test data for the condensation of pure saturated vapors.

For a Vertical Surface of height L ft., $h = 16.3(r\rho^2K^3/ZL\theta)^{1/4}$; [26]

For a Horizontal Pipe of diameter d in., $h = 23.6(r\rho^2K^3/Zd\theta)^{1/4}$, [27]

where h = heat transfer coefficient, B.t.u. per hr. per sq. ft. per deg. F.; r = latent heat of condensation, B.t.u. per lb.; ρ = density of liquid, lb. per cu. ft.; K = thermal conductivity of the liquid, B.t.u. per hr. per sq. ft. per deg. F. per 1 in.; Z = viscosity of liquid, centipoises; θ = temperature difference between the vapor and the cooling surface, deg. F. For condensing superheated vapors, h has practically the same value if θ is taken as the difference between saturation temperature and the surface temperature. In the case of a bundle of horizontal pipes, d should be taken as the sum of the diameters in a vertical row.

EFFECT OF NON-CONDENSING GASES.—The presence of even a small amount of non-condensing gas, as air, in a vapor may have a marked effect in reducing the heat transfer coefficient. Othmer (*Ind. and Engg. Chem.*, vol. xxi, 1929, p. 576) found that the presence of 1.07% of air in steam reduced the coefficient to 55% of its value for pure steam. Under the conditions of good engineering practice, the average value of h is about 2000 for steam and 1000 for ammonia, bearing in mind that these are film coefficients on the vapor side only. Values of h for other vapors usually are lower; McAdams and Frost (*Ind. and Engg. Chem.*, vol. xiv, 1924, p. 13) obtained coefficients of about 300 for carbon tetrachloride and 350 for benzine.

6. HEAT TRANSFER APPLICATIONS

CONDUCTANCE. THERMAL RESISTANCE.—It has been shown above that it is possible to express heat transfer by any of the fundamental processes in terms of an individual heat transfer coefficient h, in B.t.u. per hr. per sq. ft. per deg. F. The heat flow then is given by expression $q = hA(t_1 - t_2)$ B.t.u. per hr., where A = area, sq. ft., and t_1 and t_2 = terminal temperatures, deg. F. For the purpose of combining several processes acting in parallel or in series, to obtain the total or overall heat transfer, it is convenient to define the *Conductance*, C, of each process as the product of the coefficient

and the corresponding area; $C = hA$. The reciprocal of the conductance is the *Thermal Resistance*, $R = 1/C$. Thermal conductance and resistance then may be combined or resolved in a manner analogous to the treatment of the corresponding terms in electrical circuits, as shown below.

PARALLEL PROCESSES.—For several processes acting through parallel paths, the conductances are additive. $C = C_1 + C_2 + C_3$, etc. If two or more processes act in conjunction through the same path, or dissipate heat from the same surface, the individual coefficients may be added directly, $h = h_1 + h_2$, etc.

For example, in computing heat loss from a surface in still air, radiation coefficient, h_r should be added to convection coefficient, h_c. In many practical cases, such as non-metallic surfaces or oxidized steel pipes, the emissivity e is about 0.9. Under these conditions the value of the combined coefficient $(h_c + h_r)$ may be obtained from Table 12. The coefficients for pipes are based on tests by R. H. Heilman (*Trans.* A.S.M.E., vol. xliv, 1922, p. 299), who obtained practically the same results with horizontal bare steel pipes as with canvas covered surfaces. Very similar figures have been reported by other observers, for vertical as well as horizontal pipes. Under the conditions of forced convection at moderate temperatures the radiation component usually is so small that the total heat transfer may be obtained directly from Fig. 1.

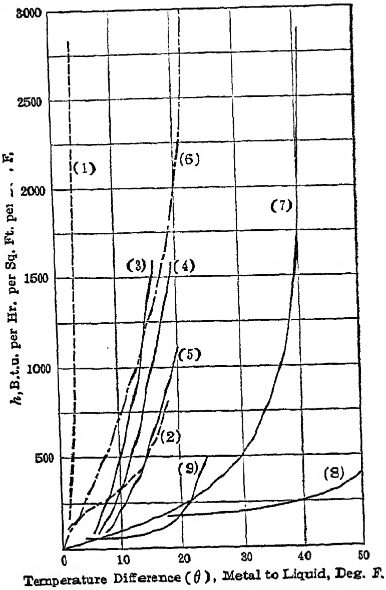

FIG. 3. Heat Transfer Coefficients, Metal to Boiling Liquids

SERIES OR OVERALL HEAT TRANSFER.—When heat flows through several paths in series, as from one fluid to another across a dividing wall, the total or overall resistance is equal to the sum of the individual resistances.

$$R = R_1 + R_2 + R_3 =$$

The heat flow in B.t.u. per hr. is then $q = (t_1 - t_2)/R$. In series flow the overall heat transfer coefficient usually is designated by the symbol U, as B.t.u. per hr. per sq. ft. per deg. overall temperature difference. If the cross-section of the heat path for all processes is the same, or if an average area is used in the case of thin-walled pipes, the reciprocals of the individual coefficients are additive. $1/U = 1/h_1 + 1/h_2 + 1/h_3$, etc. The value of h for a pipe wall is equal to the conductivity of the metal divided by the wall thickness in inches. In many practical cases, as in the exchange of heat between two fluids through a thin metal wall, the conduction coefficient of the metal is so large that its reciprocal may be left out of the equation for series flow, so that $1/U = 1/h_1 + 1/h_2$.

Table 12.—Combined Heat Transfer Coefficients $(h_c + h_r)$ for Surfaces in Still Air at Room Temperatures

(In B.t.u. per hr. per sq. ft. per deg. F.)

Pipe Size, in.	Outside Diam., in.	Temperature Difference, deg. F.								
		25	50	100	200	300	400	500	600	700
1/2	0.840	2.40	2.48	2.70	3.21	3.84	4.57	5.41	6.31	7.20
1	1.315	2.21	2.29	2.50	3.00	3.60	4.34	5.16	6.05	7.00
2	2.375	2.04	2.15	2.35	2.85	3.45	4.16	4.98	5.84	6.75
4	4.50	1.90	2.00	2.19	2.66	3.24	3.95	4.77	5.64	6.55
8	8.625	1.80	1.91	2.09	2.56	3.14	3.86	4.66	5.53	6.40
Plane Surface		1.69	1.75	2.00	2.51	3.06	3.73	4.42	5.28	6.22

In any case, the overall coefficient is always less than the smallest individual coefficient. For example, if the coefficient for air flowing over a copper tube is $h_1 = 10$ and the coefficient for water circulating through the tube is $h_2 = 500$, then $1/U = 1/10 + 1/500$, or $U = 9.8$. If the water velocity is increased until $h_2 = 1000$, the overall coefficient becomes $U = 9.9$, which shows that under such conditions the value of U is practically equal to the air film coefficient (Fig. 1). On the other hand, in the case of heat transfer from steam to water in condenser tubes or feedwater heaters, the water velocity is the limiting factor, as is shown in Table 13, based on Orrok's tests (*Trans.* A.S.M.E., vol. xxxii, 1910, p. 1139).

Table 13.—Heat Transfer from Steam to Water in Condenser Tubes

1-in. O.D., 18 B.W.G. Admiralty tubes; steam temperature, 130° F.; water temperature 55° F.

	Water Velocity, ft. per second					
	0.5	1	2	4	6	8
	Values of U, B.t.u. per hr. per sq. ft. per deg. F.					
New, clean tubes........	145	242	394	614	774	900
Old, dirty tubes.........	135	215	327	465	550	614

Many tests on surface condensers and heaters, reported in the literature, show values of U intermediate between the figures given above for old and new tubes.

OVERALL HEAT TRANSMISSION.—When heat flows from a medium at a constant temperature, t_1, to another medium at a constant temperature, t_2, deg. F., through a path having a constant or mean area, A, sq. ft., the rate of heat transfer in B.t.u. per hr. is $q = UA\theta$, where θ is the temperature difference $(t_1 - t_2)$. The value of the overall coefficient U may be computed from the individual coefficients, h_1, h_2, etc., as shown above. In heat exchangers where the temperature difference decreases from θ_a at one end of the apparatus to θ_b at the other end, an arithmetic mean $(\theta_a + \theta_b)/2$, may be used with little error if $\theta_a/\theta_b < 2$. Otherwise the logarithmic mean difference should be used as follows,

$$/2.3 \log_{10} (\theta_a/\theta_b) \quad . \quad . \quad . \quad . \quad [28]$$

This applies to any of the following cases: 1. A surface or fluid at a constant temperature exchanging heat with a flowing medium; 2. Two media flowing in opposite directions (counter flow); 3. Two media flowing in the same direction (parallel flow), provided the specific heats and heat transfer applications are sensibly constant along the surface. Methods for computing the mean temperature difference under other other conditions are given in McAdams' Heat Transmission.

EVAPORATORS AND EVAPORATION

By W. L. Badger

References.—Chemical Engineers' Handbook, Perry; McGraw-Hill, 1934; Elements of Chemical Engineering, Badger and McCabe; McGraw-Hill, 1931; Heat Transfer and Evaporation, Badger; Chemical Catalog Company, 1926; Evaporation, Webre and Robinson, Chemical Catalog Company, 1926; Evaporating, Condensing and Cooling Apparatus, Hausbrand, Wright and Heastie; Van Nostrand, 1933.

Evaporation may be carried out by the use of any suitable source of heat, but certain methods, because of their convenience and economy, are most practical. Evaporation by solar heat is practical in very few locations in the U. S., and is confined entirely to the manufacture of common salt and similar compounds. For evaporation in sprays and cooling towers, see Section 9. Evaporation by direct fire is a province of the designer of steam boilers. See Section 6. Where liquids are evaporated other than for making steam or by waste heat, the apparatus never has been standardized. Such apparatus may be designed on the basis of information in pp. 3-38 to 3-45. In most operations in practice where a solution is to be concentrated or water is to be distilled, some type of steam-heated apparatus almost invariably is used. Many types of construction are found, but certain constructions are so common as to be almost standard.

1. EVAPORATOR CONSTRUCTION

Steam-heated evaporators may be classified in three general types: Those with horizontal tubes, with inclined tubes, and with vertical tubes. The latter may be subdivided into evaporators with natural circulation and evaporators with forced circulation. Fig. 1 gives conventionalized illustrations of these types.

THE HORIZONTAL TUBE EVAPORATOR, Fig. 1-A, consists of a vertical cylindrical body, that may be from 3 to 15 ft. diam. and from 4 to 15 ft. high. Two rectangular

steam chests in the lower section contain tube sheets, between which the tubes are fastened. The tubes, usually 7/8 in. diam. in smaller evaporators, and 1 1/4 in. in larger ones, generally are fastened to the tube sheets by rubber packing rings and packing plates held down by studs. Connection for inlet and outlet of liquor may be at any convenient point. The vapor offtake always is in the center of the top. It may or may not be provided with internal or external foam catchers or entrainment separators. Steam for heating enters one steam chest, and condensate and non-condensible gases are removed from the other. This evaporator is used widely, although it is not the commonest type. It is primarily suitable for non-viscous liquids that do not deposit salt or scale during evaporation. It gradually is being replaced by other types.

THE STANDARD VERTICAL TUBE EVAPORATOR, Fig. 1-B, consists of a vertical cylindrical shell which may be closed with a flat bottom, a deep dish or a conical bottom. Vertical tubes are fastened between two horizontal tube sheets extending across the entire body near the bottom. The tubes always are held in place by rolling, and are from 1 1/2 to 4 in. diam. (2 and 2 1/2 in. are most common) and from 30 in. to 6 ft. long (5 ft. most common). A central downtake well generally is provided, of cross-sectional area of about 75% of the combined cross-sectional area of the tubes. The liquid is inside the tubes. Steam enters the space outside the tubes and between the tube sheets through suitable connections. Condensate is taken off the bottom tube sheet, and non-condensed gases usually are removed from the top tube sheet at a point opposite the steam inlet. During boiling, normal circulation is up through the tubes and back through the downtake. Connections for admitting feed and discharging thick liquor may be made where desired.

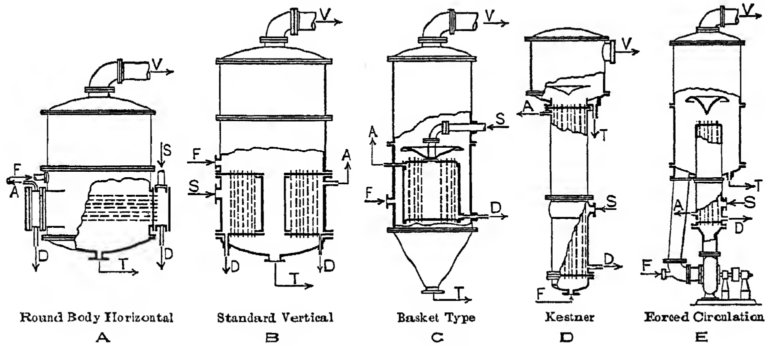

Fig. 1. Types of Evaporators

This evaporator is probably at present (1935) the most widely used of all types. It can be adapted to more different purposes and can be built in larger units than the horizontal tube evaporator. It is the only practical type for liquids that deposit salt or scale during boiling. It can carry liquids to relatively high viscosities. The construction is so common that it often is referred to as the standard evaporator.

THE BASKET-TYPE EVAPORATOR, Fig. 1-C, is a structural variation of the standard type. The downtake, instead of being a central well, is an annular ring; the heating element comprises a cylindrical drum or basket with tubes of the usual size rolled into the tube sheets. Steam generally is admitted to the top of the basket at the center. This type is quite common in the U. S. and is suitable for the same uses as the standard evaporator.

There may be many other minor variations of the standard vertical tube evaporator. The downtake may be at one side; it may consist of a number of small downtake tubes; or it may consist of downtake passages entirely external to the main body. The constructions, 1-B and 1-C, however, are the only important ones.

LONG-TUBE NATURAL CIRCULATION VERTICAL EVAPORATORS, Fig. 1-D, have tubes 15 to 20 ft. long. The liquor space is reduced to a very small chamber below the bottom tube sheet. There is a relatively small vapor head above the top tube sheet. In operation, the normal liquor level is only about 3 ft. above the bottom tube sheet, and the liquor being evaporated is carried to the top of the evaporator as a film along the tube wall. Immediately above the tubes, some type of entrainment separator deflects

the liquid into a channel, whence it is drawn off. In this type the liquor passes through the evaporator but once.

This type has been very little used in the U. S., but has been generally known abroad as the Kestner evaporator. Interest in this type is rapidly growing (1935) and it is easily possible that it may outstrip shorter tube types. It is not suitable for liquids that deposit salt or scale.

FORCED CIRCULATION EVAPORATORS, Fig. 1-E, consist of a bundle of tubes, usually $^7/_8$ in. diam. by 8 ft. long. Steam is introduced around these tubes near the bottom of the heating element, passes up behind an inner cylindrical baffle, and flows downward along the tubes. Non-condensed gases and condensate are taken off near the bottom tube sheet. A portion of the heating element projects into the main body of the evaporator. Liquid is pumped through the tubes at velocities of 6 to 12 ft. per second, usually by a low head centrifugal pump. The liquid issues from the tubes as a mixture of vapor and spray, striking a parabolic deflector that throws the liquid down into the lower part of the evaporator body, whence it returns to the circulating pump. Concentrated liquor usually is taken off from the body, and feed is introduced into the pump suction.

This evaporator is suitable for the concentration of liquids to extremely high viscosities, for liquids that tend to deposit salt or scale, for foamy liquids or cases where entrainment must be reduced to a minimum, or for cases where high-priced metals must be used for the heating surface. This evaporator, with nickel tubes, has become the standard in the U. S. for the evaporation of caustic soda.

Inclined Tube Evaporators have been popular at one time in both Europe and the U. S., but are not now offered by many of the well-known makers of evaporators. The long-tube natural-circulation type has all the advantages claimed for the inclined tubes, and requires less floor space.

Miscellaneous Types.—Many evaporators with special types of heating surfaces have been recommended at one time or another, especially for the preparation of water for boiler feed, in both stationary and marine plants. These usually have heating surfaces in the form of flat coils, hairpin tubes, or vertical coils. One of the better known types is the Griscom-Russell. It uses a number of vertical coils between two cast-iron headers, attached to a door that fits the side of a vertical cylindrical body. One advantage claimed for such evaporators, and for the Griscom-Russell evaporator in particular, is that when the surfaces become coated with hard scale, cold water may be turned into the coils and the resultant contraction cracks off the scale. These evaporators have been used only in power plant work.

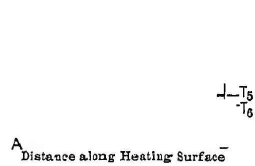

Fig. 2. Thermal Conditions in Evaporators

The purpose for which evaporators may be used and the types of liquids to be evaporated are so varied that it is impossible to make definite statements as to the principal field of usefulness of each type. In many industries the type of evaporator used is dictated by custom, rather than by sound engineering principles.

2. HEAT TRANSFER IN EVAPORATORS

The discussions of Heat Transfer (see p. 3-26) indicate that the only logical method of studying heat transfer coefficients would be to separate them into their separate film coefficients. Practically no work of this type has yet been done on boiling liquids.

Fig. 2 shows diagrammatically the thermal conditions in the evaporator in the most general cases. Temperatures are plotted on the Y axis and distance along the heating surface is plotted along the X axis. Steam enters somewhat superheated at temperature T_1 and is first cooled to saturation temperature T_2. The heating surfaces should be so proportioned that there is no appreciable pressure drop between steam inlet and condensate outlet and, therefore, condensation takes place throughout the heating surface at T_2. Before leaving the evaporator the condensate may be cooled to T_3. It is obvious that in practice these operations do not take place in three distinct stages, but are more or less simultaneous. For discussion, however, it is convenient to separate them as shown.

TEMPERATURE DIFFERENCES.—The liquid enters the evaporator somewhat below its boiling point at T_4. It then is heated to boiling point, T_5, at which temperature it evaporates throughout the body. In practically every case T_5 is higher than the boiling point of pure water, T_6, under the pressure existing in the body of the evaporator.

The true temperature difference between steam and liquid would be the area $T_1T_2T_3T_5T_4T_1$ divided by distance AB. In most cases in practice, however, the superheat temperature, the condensate temperature, and the feed temperature are neglected,

and the working temperature drop is considered to be the difference between the temperature of the steam and the temperature of the liquid.

It is much easier to measure the pressure in the vapor space of the evaporator than it is to measure temperature of the boiling liquid. It is customary, therefore, to calculate temperature T_6 from the pressure of the vapor space by means of steam tables, and the temperature difference $(T_2 - T_6)$ is termed the *apparent temperature difference.* Heat transfer coefficients based on this apparent temperature difference are called *apparent heat transfer coefficients.*

If elevation in boiling point of the solution in question is known, or can be determined, temperature T_5 is obtained by adding the known elevation in boiling points to the apparent boiling point T_6. When temperature T_5 thus obtained is subtracted from T_2, this gives a *temperature drop corrected for boiling point elevation*; the heat-transfer coefficients based on this temperature drop are called *coefficients corrected for elevation in boiling points.*

The boiling point T_6 exists only at the surface of the liquid. The lower layers of liquid are under a pressure greater than that of the vapor space and, therefore, must have a higher boiling point than the surface layers. Consequently, the true mean working temperature drop is less than either of the temperature drops described above. A correction for this effect of hydrostatic head, although important, cannot be made with certainty (due to rate of circulation of the liquid). It, therefore, ordinarily is not included in evaporator calculations.

It should be noted that in no case can the elevation in boiling points of a solution be calculated from known rules, except for solutions so dilute that they are of no practical importance. Further, the elevation in boiling point changes with changes in concentration and in pressure, and, therefore, must be determined by experiment. Many data on boiling points of pure substances are given in reference books, especially International Critical Tables, but for many commercial solutions these elevations are incorrect. Tables 1 to 4 represent the results of experiments by the author.

THE OVERALL HEAT TRANSFER COEFFICIENT in an evaporator is obviously the resultant of the steam film coefficient, the resistance of the metal wall, together with any scale it may carry, and the resistance of the liquid film. Since in most cases the liquid film is in natural or free convection, it practically is impossible to calculate overall heat transfer coefficients for any except forced circulation evaporators. In these the liquids inside the tubes may be considered as non-boiling through a considerable part of their length.

While there are many data in the literature on heat transfer coefficients in evaporators, they cover such a small portion of the entire field that the average engineer cannot predict heat transfer coefficients. To give an idea of variations that may be expected, a set of such determinations is reproduced in Fig. 3. This represents overall apparent coefficients between steam and boiling distilled water, in a vertical-tube basket-type evaporator with tubes 2 in. diam. by 30 in. long. The general shape of the curves is similar for other tube proportions. Note that the heat transfer coefficient increases with increasing temperature drop, due to more vigorous boiling at the higher temperature drops, with correspondingly more rapid circulation. Also note that for a given temperature drop the heat transfer coefficient increases as the boiling point increases. This is due largely to a decreased viscosity of water at higher temperatures, with consequent increase in rate of circulation. Changes of the same, or even greater, order of magnitude can be caused by a change in the type of liquid, depth of liquid, diameter of tubes, length of tubes, shape and size of the body, and many other factors. It is obvious that it is impossible to present in any summary a definite statement as to what heat transfer coefficient may be expected in a given case. The author has tests of evaporators showing overall heat transfer coefficients ranging from 4000 to 2 B.t.u. per sq. ft. per hr. per deg. F. In practice, unless data are available from plant tests on evaporators of the same type and size as the one under consideration, and operating under the same conditions on the same liquor, it is necessary to depend on the knowledge of the companies manufacturing commercial evaporators. In general, with ordinary non-viscous, non-scaling liquids, the horizontal-tube or the standard vertical-tube evaporator will have heat transfer coefficients between 200 and 500 B.t.u. per sq. ft. per hr. per deg. F. The long-tube natural-circulation evaporator and the forced-circulation evaporators may reach 1000 to 1200 B.t.u. in the same units.

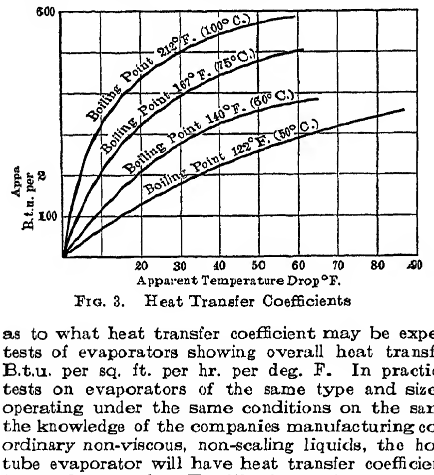

FIG. 3. Heat Transfer Coefficients

3. MULTIPLE-EFFECT EVAPORATION

A multiple-effect evaporator is a series of evaporators so connected that the vapor from one body is used as the heating steam in the next. To provide a working temperature drop in each body or effect, the pressure in the vapor space of each body must be lower than the preceding one. The individual bodies of a multiple-effect evaporator are similar in all respects to the construction of single-effect evaporators.

HEAT RELATIONS.—In Fig. 4, imagine each body to be fed with liquid heated to the boiling point for the particular body to which it is fed. Let the liquid being evaporated be either pure water or a dilute solution whose thermal properties are not appreciably different from those of pure water. Consider radiation losses to be negligible. Then if W_0 pounds of steam at pressure P_0 are fed to the heating surface of the first effect, and if condensate be assumed to leave at T_0, the saturation temperature corresponding to the pressure P_0, then W_0L_0 B.t.u. are delivered to the heating surface. L_0 = latent heat of steam at pressure P_0. The liquid is at pressure P_1 and has a boiling point of T_1. T_1

will not be greatly different from T_0 and, therefore, L_1, the latent heat of the liquid in the first effect, will be nearly the same as L_0. W_0 pounds of steam entering the first effect will evaporate W_1 pounds of water in the first effect, and W_1 and W_0 will be nearly equal.

When the vapor produced by the boiling liquid in the first effect enters the second effect it will condense at the pressure P_1 and will, therefore, have latent heat L_1 very nearly the same as L_0. The liquid in the second effect will have a latent heat of L_2, not greatly different from L_1. Therefore, W_2 also will be nearly equal to W_0. The same line of reasoning may be continued, from which it may be concluded that in an N-effect evaporator, one pound of steam will evaporate N pounds of water. In practice, this statement must be modified to take into consideration such details as heat used for heating of feed, changes in latent heats when there are very large temperature drops across the evaporator, heat losses by radiation, and similar effects. The principle remains unchanged, that increasing the number of effects increases the *economy* of operation.

RELATIVE CAPACITY OF SINGLE- AND MULTIPLE-EFFECT EVAPORATORS.—The pressure and temperature of steam for operating the evaporator, and the pressure and temperature that may be produced in a condenser, usually are fixed by conditions external to the evaporator. If T_0 is the saturation temperature of the steam available, and T_N is the saturation temperature corresponding to the pressure in the condenser, then the total temperature drop available for the operation of the evaporator is $T_0 - T_N$. If a single-effect evaporator is used, of a heating surface of A square feet and an overall coefficient U, the heat transmitted by this evaporator will be $UA\ (T_0 - T_N)$.

Suppose that a double-effect evaporator be operated with steam to the first effect at T_0 and that the pressure in the vapor space of the second effect corresponds to temperature T_N. The boiling point in the first effect (and consequently the temperature of the heating steam in the second effect) are represented by T_1. If both evaporators have the same surface A per effect, and if their heat transfer coefficients are U_2 and U_1, respectively, then the heat transferred through the first effect will be $U_1A\ (T_0 - T_1)$; the heat transferred through the second effect will be $U_2A\ (T_1 - T_N)$. If heating of feed and losses by radiation, etc., are neglected, it follows that $U_1A\ (T_0 - T_1)$ must be approximately equal to $U_2A\ (T_0 - T_1)$. That is, the evaporator will come to equilibrium with T_1 at such a value that the temperature drops in the two effects will be approximately inversely proportional to the heat transfer coefficients. Temperature T_1 cannot be set arbitrarily, or controlled mechanically, as it is solely the result of thermal equilibrium between the effects. If any operating condition changes so that U_2 decreases, then steam will not be condensed in the heating surface of the second effect as fast as it is generated in the first effect. As a result, pressure will build up in the first effect with consequent rise in temperature T_1. This will decrease the temperature drop across the first effect and increase it across the second effect until the evaporator has attained an equilibrium corresponding to the new conditions.

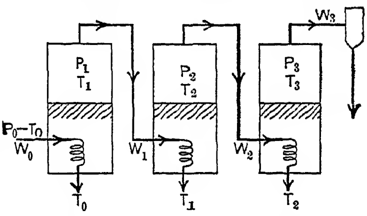

FIG. 4. Diagram of Multiple Effect

The above reasoning may be extended to any number of effects and the conclusion reached that, in a multiple-effect evaporator, the temperature distribution between effects represents a normal and automatically-attained thermal equilibrium. This cannot be altered mechanically, and will be such that the temperature drops across the various effects will be approximately inversely proportional to the heat transfer coefficients in those effects.

It will also appear from the above reasoning that, since $(T_0 - T_1)$ is only a part of the single-effect temperature drop, $(T_0 - T_N)$, A square feet of heating surface in the first effect of a double-effect evaporator will transmit much less heat than the same number of square feet in a single-effect evaporator working between the same terminal temperatures T_0 and T_N. Further, since the heat transmitted in the first effect is approximately equal to the heat transmitted in the second effect, it follows that even if the heat transfer coefficients of a double-effect evaporator were equal to the heat transfer coefficient in a single-effect evaporator, there would be needed A square feet in *each* effect of the double-effect evaporator to transmit the same total quantity of heat with the same terminal temperature drop as would be transferred by A square feet in a single-effect evaporator. This same reasoning can be continued to any number of effects, and leads to the conclusion that a multiple-effect evaporator, to have a given total evaporation, must have as much heating surface in *each* effect as the heating surface of a single-effect

evaporator operating under the same terminal temperatures. Further, Fig. 3 shows that as temperature drops decrease, heat transfer coefficients decrease. Consequently, in practice it usually is necessary to have more surface per effect in a multiple-effect evaporator than would be required in a single-effect evaporator to do the same work.

The first cost of an evaporator, and consequently fixed charges and maintenance, thus will increase in proportion to the number of effects. Another statement of the same conclusion is the capacity of the evaporator per square foot decreases in proportion to the number of effects. Consequently, although passing from single effect to multiple effect improves steam *economy*, it decreases *capacity*, and increases fixed charges. The economic number of effects for any particular case is obviously that number which shows the minimum total cost. The total cost is the result of adding steam costs and condenser water costs (which decrease with number of effects) to fixed charges and maintenance (which increase with number of effects). Such total cost curves usually show a marked minimum.

In many cases in present practice single- and double-effect evaporators are used. Triple- and quadruple-effects are very common and there are a few quintuple-effects. Evaporators with six effects or more are extremely rare.

4. CALCULATIONS FOR MULTIPLE-EFFECT EVAPORATORS

The most important results to be obtained from the preliminary calculations for multiple effect evaporators are: 1. Quantity of steam required; 2. Heating surface required; 3. Temperature in the various effects; 4. Water consumption of the condenser. As heat transfer coefficients must be determined by experience, and as they are not available to the average engineer, result (2) will be only approximate. The other results, however, will be quite accurate. These figures, especially item (1), are of the greatest importance in making preliminary decisions as to the number of effects, the arrangement of the evaporator, and its influence on the heat balance of the plant.

In Fig. 5, thin liquor is fed to the first effect, the liquor is passed from effect to effect in the direction of decreasing pressures and thick liquor is removed from the last effect. This is the commonest method of feeding evaporators.

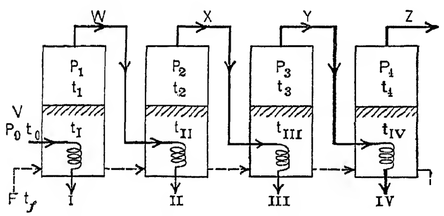

FIG. 5. Multiple-effect Calculations

In most evaporator installations, all the effects are of the same size and construction. This usually is a requisite condition in all such calculations. In order to make the calculations, approximate values of the heat transfer coefficients in different effects must be available. The most obvious method of attack would be to write heat balance equations across each effect. This, however, would involve the temperature in each effect, but, as heretofore noted, temperatures in the various effects are the results of the evaporator coming to an equilibrium determined by the relation between the heat transfer coefficients. This prevents writing a set of equations that can be solved directly, so that trial and error must be used.

EVAPORATOR CALCULATIONS.—So many evaporator arrangements and so many complicating conditions are possible that no general formulation can be made. One case will be presented with certain simplifying assumptions, and the method followed through for this case. It will be necessary to develop similar equations by methods that should be obvious for whatever arrangement may occur in practice.

In practically all cases in practice the liquid being evaporated has a higher boiling point than pure water under the same conditions. Hence the vapor leaving the liquid will be superheated. The amount of superheat contained in the vapor under ordinary circumstances will be so small a part of the total heat available from the steam that its transfer is accomplished in a very small fraction of the apparatus, and most of the heating surface will be transmitting heat from saturated steam. Therefore, it is usual to disregard the effect of superheat on the temperature drop in evaporators, but not necessarily to disregard it as it may affect heat balances.

Assumptions.—1. Condensate leaves the heating surface at the saturation temperature of the steam. 2. Radiation is negligible. 3. Superheat in the vapor does not affect the temperature difference in the next effect. 4. Secondary thermal effects such as heat

of concentration, are negligible. 5. No appreciable amount of solids separate from the liquid during evaporation. 6. Coefficients of heat transfer have been corrected for elevation in boiling point. 7. Boiling point elevations are known for the liquor in question at all concentrations and pressures. 8. Specific heat of the solution to be evaporated is 1.00 at all concentrations.

Notation.—Let I, II, III, IV = first, second, third and fourth effects respectively; F = lb. thin liquor fed per hr.; E = total evaporation, lb. per hr.; V = lb. steam used per hr.; W, X, Y, Z = evaporation in I, II, III and IV, respectively, lb.; A_1, A_2, A_3, A_4 = heating surface in I, II, III and IV, respectively, sq. ft.; t_0 = saturation temperature of steam to I, deg. F.; t_{I}, t_{II}, t_{III}, t_{IV}, = boiling point of the solution in the several effects, deg. F.; t_1, t_2, t_3, t_4 = saturation temperatures of vapor from the several effects, deg. F.; L_0, L_1, L_2, L_3, L_4 = latent heat of vaporization of steam from the solution at t_0, t_1, t_2, t_3, t_4, B.t.u.; h_0, h_1, h_2, h_3, h_4 = heat present as superheat in vapor from the various effects, B.t.u.; U_1, U_2, U_3, U_4 = overall heat transfer coefficients in the various effects, corrected for elevation of boiling point. t_f = temperature of feed, deg. F.; Δt_1, Δt_2, Δt_3, Δt_4 = net working temperature drops in the various effects, deg. F.

Heat Balance Equations are as follows:

Across I. $$V(L_0 + h_0) = F(t_{\text{I}} - t_f) + W(L_1 + h_1) \qquad [1]$$

Across II. $$W(L_1 + h_1) + (F - W)(t_{\text{I}} - t_{\text{II}}) = X(L_2 + h_2) \qquad [2]$$

Across III. $$X(L_2 + h_2) + (F - W - X)(t_{\text{II}} - t_{\text{III}}) = Y(L_3 + h_3) \qquad [3]$$

Across IV. $$Y(L_3 + h_3) + (F - W - X - Y)(t_{\text{III}} - t_{\text{IV}}) = Z(L_4 + h_4) \qquad [4]$$

Material Balance.—In addition to the foregoing, a material balance equation can be 'tten:

$$E = W + X + Y + Z \qquad [5]$$

Heating Surface and Heat Transfer.—Next a set of equations connecting the heating surface and the heat transfer in each effect may be written:

$$A_1 = \frac{V(L_0 + h_0)}{U_1\,(t_0 - t_{\text{I}})} = \frac{W(L_1 + h_1) + F(t_{\text{I}} - t_f)}{U_1(t_0 - t_1)} \qquad [6]$$

$$\frac{+\ h_1)}{-\ t_{\text{II}})} \qquad [7]$$

$$A_3 = \frac{X(L_2 + h_2)}{U_3(t_2 - t_{\text{III}})} \qquad [8]$$

$$A_4 = \frac{Y(L_3 + h_3)}{U_4(t_3 - t_{\text{IV}})} \qquad [9]$$

The steps in the solution are as follows: 1. An approximation is made of the values of W, X, Y and Z; from these the approximate concentrations in each effect is determined. 2. From this approximate concentration the elevation in boiling point in each effect is determined. 3. The pressure and temperature of steam to the first effect and the vacuum to be maintained in the last effect usually are available as fixed conditions in the problem. If not, values for them are assumed, and from these, total available temperature drop for the whole evaporator is determined. 4. From the total available temperature drop, the sum of the elevations in boiling point is subtracted and the remaining net or effective temperature drop is divided between the effects, approximately inversely to the heat transfer coefficients. This, with the approximate elevation in boiling point, gives the temperature of liquid and the saturation temperature of vapor for each effect. 5. On the basis of these assumed temperatures the heat balance equations are solved for V, W, X, Y, and Z. 6. On the basis of these values for evaporation in each effect, the heat transfer equations are solved for the surface in each effect. 7. If these surfaces are not sensibly equal (assuming that it is a condition of the problem that all evaporator bodies must be of the same size), the temperatures in the various bodies are readjusted and steps 4, 5 and 6 are repeated. This process is continued until a set of temperatures is found that will give results satisfying the condition that all heating surfaces are equal. Values for V and Z thus obtained ordinarily are carried to within a few percent. If final values for W, X, Y and Z result in concentrations so different from those assumed in step 1 that the preliminary elevations in boiling point determined in step 2 are incorrect by more than one or two degrees then the calculations must be repeated on the basis of the new values for elevations of boiling point. Although the method sounds tedious, it is usually possible with a little experience to make the second or third trial yield results with an accuracy ample for any preliminary calculations. The following example will illustrate the application of the method.

Example.—A quadruple-effect evaporator is to be fed with 50,000 lb. per hr. of 5% sodium chloride solution at 150° F. Steam to the first effect will be at 35 lb. per sq. in., gage. Vacuum on

the last effect will be 26 in. referred to a 30-in. barometer. The solution is to be concentrated to 25% solids. Required the approximate heating surface, the steam used, and the heat above 32° F. going to the condenser.

Assumptions.—1. Feed will be forward. 2. Radiation losses will be negligible. 3. All specific heats may be taken as 1.00. 4. There will be no appreciable heat of concentration. 5. All condensate will leave steam chests at saturation temperature. 6. All effects are to have the same heating surface. 7. Superheat in vapor due to elevation in boiling point will not affect temperature drop in next effect. 8. Coefficients, in B.t.u. per hr. per sq. ft. per deg. F., corrected for elevation in boiling point, will be: First-effect, 375; second effect, 350; third effect, 300; fourth effect, 200. 9. Elevation in boiling point of salt solution may be taken from Table 1. 10. No salt or scale will separate. 11. Steam to the first effect is dry and saturated.

Solution.—*Step* 1. The total evaporation is determined as follows:

	H_2O	NaCl	Total
Feed	47,500 pounds	2,500 pounds	50,000 pounds
Product	7,500 "	2,500 "	10,000 "
Evaporation	40,000 pounds		40,000 pounds

Assume that the evaporation will be approximately equal in all effects. Then the concentrations will be as follows:

	H_2O, lb.	NaCl, lb.	Total, lb.	Concentration
Feed to I	47,500	2,500	50,000	5.00%
Evaporation in I	10,000		10,000	
Feed to II	37,500	2,500	40,000	6.25%
Evaporation in II	10,000		10,000	
Feed to III	27,500	2,500	30,000	8.33%
Evaporation in III	10,000		10,000	
Feed to IV	17,500	2,500	20,000	12.50%
Evaporation in IV	10,000		10,000	
Product	7,500	2,500	10,000	25.00%

Step 2. The elevations will be approximately as follows.

Effect	First	Second	Third	Fourth
Concentration	6.25%	8.33%	12.50%	25.00%
Elevation, deg. F.	1	2	3	10

Step 3. Steam to first effect—35 lb. gage = 281° F.
Vacuum on last effect—26 in. = 125° F.
Total temperature drop = 156° F.

Step 4. Total available temperature drop = 156° F.
Sum of all boiling point elevations = 16° F.
Net temperature drop = 140° F.

After several trials it is found that the desired temperature drops are $\Delta t_1 = 35°$; $\Delta t_2 = 25°$; $\Delta t_3 = 31°$; $\Delta t_4 = 49°$. The conditions will be

		Latent heat, B.t.u.	Superheat, B.t.u.	$L + h$
Steam to I	281° F.	923.5	......	923.5
Δt_1 =	35			
Boiling point in I =	246			
Elevation in I =	1			
t_1 =	245	948.6	0.5	949.1
Δt_2 =	25			
Boiling point in II =	220			
Elevation in II =	2			
t_2 =	218	966.4	1.0	967.4
Boiling point in III =	187			
Elevation in III =	3			
		987.4	1.5	988.9
Boiling point in IV	135			
Elevation in IV =	10			
t_4 =	125	1022.2	5.0	1027.2

Step 5. Substituting in Equations [2], [3], [4] and [5] gives

$$949.1W + (50{,}000 - W)(246 - 220) = 967.4$$
$$967.4 + (50{,}000 - W - X)(220 - 187) = 988.9Y$$
$$988.9Y + (50{,}000 - W - X - Y)(187 - 135) = 1027.2Z$$
$$W + X + Y + Z = 40{,}000$$

A simultaneous solution of these equations gives W = 8690 lb.; X = 9650 lb.; Y = 10,500 lb., Z = 11,160 lb.

Step 6. Substituting in Equations [6], [7], [8], and [9], gives $A_1 = 1014$ sq. ft.; $A_2 = 972$ sq. ft.; $A_3 = 1007$ sq. ft.; $A_4 = 998$ sq. ft.; or an average of 1000 sq. ft. per effect.

Since the values for the coefficients are only approximate, and since a closer correspondenc

32° F. in the vapor going to the condenser is $11{,}160 \times (1027.2 + 125 - 32)$ 12,389,800 B.t.u.

If any of the assumptions made on page 3-44 in connection with this problem are not justified, the resulting modification of the above equations and methods will be obvious.

5. EXTRA STEAM

The phrase "extra steam" has a special meaning in connection with evaporator flow sheets. It means vapor withdrawn from any body of an evaporator for use elsewhere in the plant.

In a plant having a complicated steam flow sheet, especially as regards the use of process steam, the possibilities of a multiple-effect evaporator as a producer of low-pressure steam rarely is given sufficient consideration. For instance, if vapor is taken from the second effect of a multiple-effect evaporator for use as process steam, providing that the temperature of the second effect is sufficiently high for the purpose desired, this vapor may be considered as steam that has already evaporated twice its weight of water and is therefore that much more economical than steam from the mains. The removal of such quantities of vapor from a multiple-effect evaporator alters the evaporator balance somewhat, and makes the evaporator, as an evaporator, somewhat less economical. However, the effect on the heat balance of the plant as a whole is always highly favorable. If large quantities are withdrawn from any one body in comparison to the amount generated in that body, the temperature distribution over the evaporator may be too much disturbed. It may then be more practical to put additional heating surface in the body from which such vapor is withdrawn and all bodies ahead of it. If the amount withdrawn is 25% or less of the total amount generated in any given body, it usually still will be possible to make all bodies alike without having abnormal operating conditions. The advantages of this method of operation are fully understood only in the beet sugar industry. They deserve much more consideration in other industries than they have had heretofore.

6. EVAPORATOR OPERATION

OPERATING TEMPERATURES.—The pressure of the steam to the first effect of an evaporator usually is fixed by conditions already existing in the plant. When a new plant is to be planned, that will use steam both for generating power and for evaporating, rather extensive calculations are necessary to determine the point at which prime movers should exhaust to evaporators. Evaporator practice was developed when power generally was obtained from small non-condensing reciprocating engines, and a general impression resulted that most evaporators should be given steam at from 5 to 25 lb. gage. This is by no means necessary, and evaporators are in operation with steam pressures on the first effect anywhere from 125 lb. gage down to 22 in. vaccuum.

The vacuum on the last effect is not so easily determined. When evaporators operated with steam at about 5 lb. gage, a vacuum of 26 in. was about all that ever was expected, and has become quite customary in evaporator practice. It is, however, a mistake to assume that because power plant engineering has developed devices capable of producing much higher vacuums economically, these devices should be applied to evaporators and the highest possible operating vacuum used.

A vacuum sometimes is carried on an evaporator for the express purpose of boiling a heat-sensitive liquid at the lowest possible temperature. The effect of boiling point on the properties of the liquid in question then determines the vacuum to be used, and outweighs all other considerations. In the great majority of cases, however, vacuum is used merely to give a larger temperature drop across the evaporator. It would at once seem that slightly increasing the vacuum would make a relatively large difference in the total available temperature drop, and that therefore the highest possible vacuum should be carried on the last effect. Fig. 3 shows, however, that everything else being equal, the lower the boiling point, the smaller will be the heat transfer coefficient. This is because the viscosity of all liquids changes rapidly with temperature. Lowering the boiling point increases the viscosity; increasing the viscosity slows the circulation; slowing the circula-

tion gives lower heat transfer coefficients. In a multiple-effect evaporator where the temperature drops per effect are not too large, the vacuum on the last effect can be increased to the point where a lowering of the boiling point in the last effect decreases the heat transfer coefficient more than it increases the temperature drop, and, therefore, decreases the capacity of the evaporator. For this reason, very high vacuums are not desirable on evaporators, and the elaborate devices used in power plants have no place in evaporator practice.

It is not possible to make any definite statement regarding the optimum vacuum; this varies with the liquid, with type of evaporator, with number of effects, with total available temperature drop and other factors. In general, however, there are probably few evaporator installations where a vacuum of over 28 in. is justified, and in many installations the optimum vacuum probably is around 26 in. A determination of the optimum vacuum obviously will consider, not only the capacity of the evaporator, but the cost of producing the higher vacuum.

In fixing maximum and minimum temperatures in multiple-effect evaporators, consideration also must be given to the fact that, in natural circulation evaporators, the smaller the temperature drop per effect the lower will be the average coefficients, and therefore the larger the evaporator must be for a given purpose. When a natural circulation evaporator is operated on too small temperature drops, circulation stops, the liquid lies quiet and merely simmers on the surface, and the capacity is negligible. This minimum operating temperature drop varies with the type of evaporator and the characteristics of the liquid; it is usually in the neighborhood of 10 to 15° F. This limits the number of effects that can be included in any particular total temperature drop or, conversely, fixes the minimum total temperature difference over a given number of effects.

METHODS OF FEEDING.—Forward Feed. The simplest method of feeding a multiple-effect evaporator is to feed thin liquor into the first effect, pass it progressively from effect to effect, and withdraw it from the last effect. This method usually is known as forward feed. It involves only one pump with its suction under vacuum, and most of the control is by simple throttle valves. If the feed is very cold, however, larger and larger amounts of steam are condensed in the first effect to heat the liquid from the feed temperature to boiling point. Since steam so condensed yields no vapor to be used in succeeding effects, lowering the temperature of the feed increases the steam consumption per pound of evaporation.

Backward feed consists in feeding thin liquor to the last or lowest pressure effect, and withdrawing thick liquor from the first or highest pressure effect. This requires more feed pumps and somewhat more difficult control. If the feed is colder than the boiling point in the last effect, it is heated by steam that has already evaporated several times its weight of water, and in passing from effect to effect it also is heated each time by steam that already has done some work. Consequently, for cold feed, backward feed is the most economical. However, if the feed is hotter than the boiling point in the last effect it flashes down to the temperature of the last effect, and this vapor goes directly to the condenser.

In general, with low feed temperatures, backward feed should be used, and forward feed with high feed temperatures. There is a wide range of intermediate feed temperatures where the proper arrangements can be determined only by making the complete evaporator calculations for both methods.

Parallel feed usually means feeding directly into each body of a multiple-effect evaporator. This is done only when there is no thick liquor to be removed, as in the case of salt evaporators.

Mixed feed covers all other arrangements. In the particular case of liquid to be finished at high densities and high viscosities, it may be desirable to finish this liquid in the first effect in order to have the viscosity as low as possible, and yet other circumstances may call for a forward feed. In such a case a feed order II, III, IV, I, may be the most satisfactory solution. Similar considerations lead to the development of other special cases.

FOAM AND ENTRAINMENT.—These two terms should be used in different senses. Foam is the formation of a solid mat of stable bubbles. Entrainment is the carrying of either single bubbles or solid drops of liquid with the vapor. Both may occasion further difficulty or serious loss in evaporator operation.

Foam.—The causes of foam are not well understood, but it is known that in liquids having a tendency to foam, the condition is greatly aggravated by the presence of finely divided suspended matter. Operation of evaporators with foamy liquids is extremely difficult. However, low liquid levels or jets of live steam directed against the surface of the blanket may break down the foam. For a true foam, entrainment separators are of no use. Foam also may be broken down by causing it to impinge at very high veloci-

ties against the baffle. This probably explains the success of the Yaryan type natural circulation evaporator and of the forced circulation evaporator in handling foamy liquids.

Entrainment is the net result of the velocity at which particles of liquid are shot up from the boiling surface and the velocity of the vapor into which they are projected. Entrainment can be eliminated by baffles in the vapor space, by high liquid levels in natural circulation evaporators, or by keeping vapor velocities low. Vapor that leaves the body of an evaporator carrying liquid in suspension usually can be made to drop its entrainment only by causing the liquid particles to impinge against a solid surface. This is effected by entrainment separators where the steam either is turned around sharp corners at high velocity or given a circular motion. In either case, the momentum of the liquid particles throws them out of the stream of steam and against a surface where they can collect. The result of the few tests that have been made in practice is that entrainment separators are more effective as the velocity of the steam through them is increased, though this increase in velocity can be carried to a point where it causes serious pressure drops.

SCALE.—The formation of scale on the heating surface depends, not on the presence of solids of low solubility, but on the presence of solids with an inverted solubility curve, that is, solids whose solubility decreases as temperature increases. This means that in the film of liquid against the heating surface, where the highest temperatures exist, the solubility of the substance in question is the least. It therefore precipitates next the heating surface rather than in the bulk of the solution. Calcium sulphate is probably the most universal scale producing substance. Sodium sulphate and sodium carbonate are important when present in such amounts that the solution becomes saturated with them. Many other substances may form scale under certain conditions.

It rarely is possible, because of the cost involved, to pre-treat the solution to remove scale-forming substances. The problem is usually the one of so operating that scale formation shall be at a minimum. The theory of scale formation indicates that if the stagnant film be kept as thin as possible or be torn off as frequently as possible, scale formation will be at a minimum. This is proved in practice, where it is found that all factors which increase the velocity of circulation decrease the rate of scale formation. This is especially true in the forced circulation evaporator. It should be emphasized that such methods cannot, in general, prevent scale formation, but merely decrease the rate of scale formation, and, therefore, increase the time between cleanings.

Scale may be removed from evaporator tubes by any of the usual mechanical methods. Some scales can be dissolved in water; others can be dissolved by the proper chemical treatment. There is now (1935) on the market muriatic acid containing an inhibitor that does not affect its action on calcium carbonate scale or rust, but which does practically stop its action on metallic iron. Most evaporators safely can be boiled out with such a solution.

REMOVAL OF CONDENSED WATER AND NON-CONDENSED GASES.—Condensed water from the first effect is distilled water and should be returned directly to the boilers as boiler feed. Condensate from the later effects will be more or less contaminated by entrained liquid and, according to the type of substance involved and the amount of entrainment, may or may not be suitable for boiler feed make-up. Where it is not so used, condensate from one effect may be flashed down to the temperature of the next effect in a suitable receiver, combined with the condensate of the next effect and flashed down to the temperature of the following one. Unless the evaporator is very large, or the temperature drops across the individual effects very great, this method usually is too complicated to be worth while. Condensate may be removed by reciprocating pumps, self-priming centrifugal pumps, or traps. In some cases condensate pumps may be located far enough below the evaporators so that their suction connections are not under vacuum, and any type of pump then may be used.

The presence of non-condensed gases in steam gradually lowers the rate of heat transfer. Such non-condensed gases are always present, and provision must be made for their removal in any evaporator installation. In a multiple-effect evaporator, the non-condensed gases in all effects after the first will be increased by air dissolved in the solution being evaporated, by air drawn in through leaks or, in some cases, by gases generated as a result of chemical changes in the solution itself. This last, for instance, is the most important source of non-condensed gases in evaporating sugar-beet juices.

Where the amount of gas to be removed is small it is customary to have a connection from the far end of the steam chest to the vapor space of the same body. This passes the gases along from effect to effect, but, if their amount is small, a harmful concentration will not be reached even in the last effect. This method has the advantage that if the vent valves are open too wide, so that steam is vented also, this steam is not lost

but is used in succeeding effects. Where the amount of gas to be removed is large, it may be more practical to vent each effect directly to the condenser.

EVAPORATOR AUXILIARIES.—No special comments are necessary. Pumps for all purposes can be any type that is suitable for the liquor being handled, the heads against which they must work, and the possibility of vacuum on the suction side. Condensers and vacuum producing devices may be any type dictated by practice. Unless the vapor from the last effect is required for some other purpose, or unless an extremely high vacuum must be carried, surface condensers generally are too expensive, both in first cost and in water consumption, for evaporator practice. Evaporator practice regularly uses the direct-contact jet condenser, and since high vacuums seldom are required, a reciprocating vacuum pump with a Corliss type valve is at present (1935) more common than steam-jet ejectors.

7. EVAPORATION TO THE ATMOSPHERE *

EVAPORATION OF WATER FROM TANKS AND RESERVOIRS (Tech. Bull. 271, U. S. Dept. of Agriculture, Dec., 1931).—A series of experiments extending from 1923 to 1930 to determine the evaporation from tanks, reservoirs, open channels, etc., developed the formulas:

For Tanks, $E = (1.465 - 0.0186B)(0.44 + 0.118W)(e_s - e_d)$ . . . . [10]

For Reservoirs, $E = 0.771(1.465 - 0.0186B)(0.44 + 0.118W)(e_s - e_d)$ . . . [11]

where E = evaporation, in., per 24 hr.; B = mean barometer reading, in. of mercury at 30° F.; W = mean velocity of ground wind or water surface wind, mi. per hr.; e_s = mean vapor pressure of saturated vapor at temperature of water surface, in. of mercury; e_d = mean vapor pressure of saturated air at temperature of dew point, in. of mercury. Values of the factor $(1.465 - 0.0186B)$ for various altitudes are given in Table 5.

Table 5.—Value of Factor $(1.465 - 0.0186\,B)$ for Various Altitudes

Altitude above Sea-level, ft.	Barometer, in. of Hg	Factor	Altitude above Sea-level, ft.	Barometer, in. of Hg	Factor	Altitude above Sea-level, ft.	Barometer, in. of Hg	Factor	Altitude above Sea-level, ft.	Barometer, in. of Hg	Factor

DRYERS AND DRYING

By Francis E. Finch

1. CHARACTERISTICS OF DRYERS AND MATERIALS

A dryer is an apparatus for driving off moisture by the application of heat to the material, either by direct or indirect means. Thus, it differs from a dehydrator, such as a filter press or a centrifugal, which extract moisture by mechanical means; and from a calciner, which drives off volatiles, etc., by roasting at a high temperature. The calciner is used occasionally as a combined dryer and roaster, but the shell then is longer than is necessary for roasting alone.

CHARACTERISTICS OF DRYERS.—Where continuous drying is desired, it is necessary to separate the problem into, and to balance, three fundamental parts: 1. Application of heat to the material or to the air mixture which is to absorb the moisture. 2. Means for removing the water vapor, steam or mixture. This includes a study of the vapor pressures involved. 3. Conveying the material, in its wet, semi-dried and dried condition, into, through, and out of the apparatus, giving the material the proper time and contact with the heating- and moisture-absorbing elements.

The various methods of heating dryers are: *a.* By direct or indirect furnace gases, generated by coal, wood, oil, gas or other fuel; *b.* by steam, either exhaust or direct from the boiler. Steam is a most efficient means for rack or batch drying. Superheated steam or steam at high pressure has not been found efficient for continuous dryers, due to

* Staff contribution.

difficulties in mechanical construction and because superheated steam has low capacity for transferring heat; *c.* by warm air from a warm air furnace, bank of steam coils or one of the newer steam heaters.

The usual means of removing moisture driven off from the material is an exhaust fan; in some cases a stack is used. The fan impeller should have few blades, for if dust is drawn off with the moisture, it must pass through the fan unless a dust eliminator is used between dryer and fan. Stacks are satisfactory only with fairly high and uniform exhaust temperatures. With a stack, close regulation and rapid changes in draft conditions are hard to obtain. With either fan or stack, the temperature of the exhaust should be kept above the dew point, or condensation will occur in the exhaust system.

Conveying material into, through, and out of the dryer depends on the material to be dried and type of dryer selected. The thermal efficiency and capacity of the dryer depend greatly on the manner in which material travels through the drying machine.

At present (1935) several hundred different designs of drying machines are built. Therefore, the selection of a dryer for a given purpose involves the problems as above given, and also many other considerations. No certain type of dryer can be said to be the best, except when it is applied to one definite drying problem. The type, design and size of dryer selected for such definite problem must take into account the material handled, available sources of fuel or heat, space occupied, operating labor required, available power, cost of erection, upkeep or repair cost, and, last and most important, whether that type and size will give the desired product at the lowest cost. In considering the last, thermal efficiency, materials used in construction, and interest and depreciation on erected cost usually are the most important.

RELATION OF MATERIAL CHARACTERISTICS TO METHOD OF DRYING.—The varying physical and chemical properties of materials require different methods of drying. Therefore it is best to classify materials, as far as possible, into groups and have different types of dryers, each type having designs along the same general principles, for each group. To group the materials and select the proper type, the information needed is: 1. Amount of free moisture in material as fed to dryer. 2. Specific gravity of dry material. 3. Specific heat of material. 4. Size of feed to dryer. 5. Amount of free moisture allowable in material as discharged from dryer. 6. Maximum temperature to which material may be heated without undergoing undesirable chemical change or without danger of ignition. 7. Whether or not material will be injured by contact with products of combustion. 8. Action of the material as the free moisture is driven off. This usually is one of the physical properties of the material but occasionally is also a chemical one. These classified groups are:

Group A.—Materials which may be heated to high temperatures without injury by contact with products of combustion. Such materials are trap rock, limestone, sand, gravel, slag, some ores, concentrates and clays. The simplest dryer for such materials is a single revolving drum with lifters attached inside. The drum rests on supporting rollers, and has a furnace at one end and a stack or fan at the other. This type has the advantages of low first cost and accessibility for cleaning or repairs. The disadvantages are excessive fuel consumption and, if material is fed from stack to furnace end, large radiation losses and high cost of repairs to drum. If the feed is reversed, exhaust temperatures must be kept well above 212° F. to avoid recondensation and material again becoming wet. Drying to a low final moisture content is difficult if the gases travel parallel to the flow of material. Improvements on some designs of this type of dryer have eliminated some disadvantages.

Group B.—Materials which cannot come in contact with products of combustion, but which are not injured by high temperature. These are kaolin, talc rock, fuller's earth, china clay, some salts, etc. They may be dried by passing through a single drum dryer encased in brickwork. The heat is applied to the outside of the drum, and the products of combustion do not come in contact with the material. This machine is uneconomical to operate, due to the high temperature of escaping gases and high cost and frequency of repairs. Various types of patented indirect heat dryers, with the heat applied through inside tubes or other means, are much more economical to operate.

Group C.—Materials not injured by products of combustion, but which can stand only temperatures of 212° to 400° F. due to danger of ignition or chemical changes. Such materials are bituminous coal, lignite, petroleum coke, wood chips, sawdust, gypsum, various chemicals and fertilizer materials. These may be dried in the single drum and also the "bricked-in" type of dryer, but neither are satisfactory due to high operating costs, danger of ignition and explosions or chemical decomposition. Several designs of semi-direct heat types of dryers using two passes of the furnace gases inside of one revolving drum are more efficient and have lower operating costs.

Group D.—Organic materials which are used for food, as grains, corn germs breakfast

foods, starch foods, cotton seed; chemicals, as nitrate of ammonia, carbonate of potash, etc. These must be dried at low temperatures and some, such as food products, cannot be contaminated by products of combustion. For such materials, dryers of two types usually are used. Both types use live or exhaust steam as their heating medium. One type is a revolving drum with steam pipes attached inside of and revolving with the drum. The other type is a single shell dryer with steam pipes or other steam heater substituted for the furnace. Many arrangements of both types are available.

Group E comprises the largest in number of materials to be dried, and is the most varied. It contains those materials and products which cannot be agitated, due to their physical properties. Among them are ceramic wares, knitted and dyed products, very finely divided materials, extremely sticky materials, etc. For these, drying racks heated by steam or furnace, vacuum dryers, pan dryers and conveying chain dryers of many types are used. Most dryers of this type are designed for one particular product or installation.

Note: The above grouping of materials can be only general. Due to the many designs of dryers now built, a material may be dried economically in the type best suited to another group, modifications and improvements having been made in a certain design, enabling that one design to cover a broader field.

EFFICIENCY OF DRYERS.—The thermal efficiency of a dryer is the ratio of the theoretical heat required to the total heat supplied to it. When the dryer has its own separate furnace, the heat losses of the furnace are taken as part of the heat losses of the dryer. Heat losses in a dryer are: Radiation, 4 to 30%; in waste gases, 7 to 40%; in dried material, 3 to 25%. These losses may be kept near the minimum by proper design and operation.

A well-designed dryer for materials in Group A will have 70 to 82% efficiency; a single-shell dryer of good design, 45 to 60%; a "bricked-in" direct heat dryer, 50 to 65%. A properly designed indirect heat dryer for materials in group B will have, with good operation, as high as 67% efficiency, while improperly designed machines may run as low as 25%. Well designed and well operated dryers for materials in Group C will have 72 to 78% efficiency. For the various materials in Groups D and E, the best designed dryers will have efficiencies of about 60%, while some of poor design have efficiencies as low as 12%.

2. PERFORMANCE OF DRYERS

STEAM HEATED DRYERS.—Rotary Dryer with Pipes Attached to Inside of Drum.—Material, grain. Original moisture, 19%. Final moisture, 1.2%. Dried material per hour, 3820 lb. Water evaporated per hr., 985 lb. Steam consumed per hr., 1540 lb. at 10 lb. gage pressure. Power used, 18 Hp. for drum; 4 Hp. for fan. Temperature of feed, 65° F.; of discharged material, 214° F. Thermal efficiency, 83.4%, not including boiler efficiency.

Rotary Single-Shell Dryer with Bank of Steam Coils at discharge end, fan at feed end. Material, ammonium sulphate. Original moisture, 2.82%. Final moisture,

Table 1.—Performance of Various Types of Rotary Dryers

Type of Dryer	Single-shell. Direct Heat	Single-shell. Bricked-in. Direct Heat	Single-shell. Special Baffles. Direct Heat	Double-shell. Direct Heat	Double-shell. Indirect Heat	Single-shell. Bricked-in. Direct Heat
Material	Limestone	Coal	Zinc concentrates	Silica Sand	Kaolin	Talc Rock
Delivered weight, per hr., lb.	114,000	14,200	13,500	22,000	18,500	8,800
Moisture, initial, percent	5.2	8.6	12.5	11.5	19.8	7.9
Moisture, final, percent	0.3	1.2	3.2	0.6	1.3	0.8
Heat value of fuel, B.t.u.	14,000	12,100	13,200	13,500	13,800	13,200
Fuel consumed per hr., lb	1,260	248	245	360	636	205
Water evaporated per hr., lb.	5,892	1,150	1,434	2,709	4,267	689
Water evaporated per lb. of fuel, lb.	4.67	4.63	5.85	7.52	6.71	3.36
Fuel per ton of dried material, lb.	22.1	34.9	36.3	32.8	68.7	46.6
Heat lost in exhaust, percent	20.8	21.4	17.1	12.1	18.7	25.7
Heat lost in radiation, percent	19.3	19.4	20.4	11.3	18.9	23.3
Heat used to raise temp. of material, percent	20.5	15.5	12.9	14.3	6.8	12.1
Heat used to evaporate water, percent	39.4	43.7	49.6	62.3	55.6	28.9
Thermal efficiency, percent	59.9	59.2	62.5	76.6	62.4	41.0

0.08%. Dried material per hour, 12,100 lb. Water evaporated, 351.4 lb. Steam consumed per hour, 1060 lb. at 15 lb. gage pressure. Power used, 11 Hp. for drum; 4 Hp. for fan. Temperature of feed, 52° F.; of discharged material, 182° F. Thermal efficiency, 78.7% not including boiler efficiency.

Steam Tray Dryer.—Material, pigment. Original moisture, 82%. Final moisture, 0.12%. Material dried in 16 hr., dry weight, 642 lb. Temperature in drying chamber, 216° F. Thickness of material in trays, 1.4 in. Steam pressure, 26 lb. Steam consumed per lb. of water evaporated, 3.19 lb.

RABBLE AND HEARTH DRYER.—Hearth of 360 sq. ft. with mechanically-operated steel rabbles. Heat generated in Dutch oven type of furnace, gases of combustion passing underneath hearths, heating the material indirectly. Material, lead flotation concentrates. Original moisture, 13%. Final moisture, 6.5%. Weight of dried material, 6200 lb. per hour. Water evaporated, 469 lb. Fuel used per hour, 160 lb. of 11,000 B.t.u. coal. Water evaporated per lb. of fuel, 2.93 lb. Temperature of dried material, 214° F. Thermal efficiency of dryer, 40.05%.

Table 2.—Water Evaporated and Heat Required for Drying*

M = percentage of moisture in material to be dried. Q = lb. water evaporated per ton (2000 lb.) of dry material. H = B.t u. required for drying, per ton of dry material

M	Q	H	M	Q	H	M	Q	H
1	20.2	85,624	14	325.6	424,884	35	1,077	1,269,240
2	40.8	108,696	15	352.9	458,248	40	1,333	1,555,960
3	61.9	130,424	16	381.0	489,720	45	1,636	1,895,320
4	83.3	156,296	17	409.6	521,752	50	2,000	2,303,000
5	105.3	180,936	18	439.0	554,680	55	2,444	2,800,280
6	127.7	206,024	19	469.1	588,392	60	3,000	3,423,000
7	150.5	231,560	20	500.0	623,000	65	3,714	4,222,680
8	173.9	257,768	21	531.6	658,392	70	4,667	5,290,040
9	197.8	284,536	22	564.1	694,792	75	6,000	6,783,000
10	222.2	311,864	23	597.4	732,088	80	8,000	9,023,000
11	247.2	339,864	24	631.6	770,392	85	11,333	12,755,960
12	272.7	368,424	25	666.7	809,704	90	18,000	20,223,000
13	298.9	397,768	30	857.0	1,022,840	95	38,000	42,623,000

*Formulas: $Q = 2000\ M/(100 - M)$; $H = 1120\ Q \div 63{,}000$.

The value of H is found on the assumption that the moisture is heated from 62° to 212° F. and evaporated at that temperature, and that the specific heat of the material is 0.21; $[2000 \times (212 - 62) \times 0.21] = 63{,}000$.

3. DRYER DESIGN

CALCULATIONS FOR DESIGN OF DRYING APPARATUS.—A most efficient system of drying of moist materials consists in a continuous circulation of a volume of warm dry air over or through the moist material, then passing the air charged with moisture over the cold surfaces of condenser coils to remove the moisture, then heating the same air by steam-heating coils or other means, and again passing it over the material. In the design of apparatus to work on this system it is necessary to know the amount of moisture to be removed in a given time, and to calculate the volume of air that will carry that moisture at the temperature at which it leaves the material, making allowance for the fact that the moist, warm air on leaving the material may not be fully saturated, and for the fact that the cooled air is nearly or fully saturated at the temperature at which it leaves the cooling coils. A paper by Wm. M. Grosvenor, read before the Am. Inst. of Chemical Engineers (*Heat. and Vent. Mag.*, May, 1909) contains a "humidity table" and a "humidity chart" which greatly facilitate the calculations required. Table 3 is a condensation of the original table. It is based on the following data:

$D_a + 0.04\%\ CO_2 = 0.001293052/(1 + 0.00367 \times \text{Temp. deg. C.})$ kg. per cu. meter;
$D_w = 0.62186 \times D_a$,

where D_a and D_w = respectively, density of air and water vapor. Density at partial pressure ÷ density at 760 m.m. = partial pressure ÷ 760 m.m. Specific heat of water vapor = 0.475; specific heat of air = 0.2373. Kg. per cu. meter × 0.062428 = lb. per cu. ft. Compare also the tables of H. M. Prevost Murphy, p. 1–06. These latter tables are useful in calculating the amount of air necessary to absorb moisture, for any and all drying problems.

The term "humid heat" in Table 3 is defined as the B.t.u. required to raise 1° F. one pound of air plus the vapor it may carry when saturated at the given temperature and pressure; "humid volume" is the volume of one pound of air when saturated at the given temperature and pressure.

Table 3.—Humidity Tables for Drying Calculations

Temp., deg. F.	Vapor Tension, Milli-meters of Mercury	Water Vapor per lb. of Air, lb.	Humid Heat, B.t.u.	Humid Volume, cu. ft.	Density, lb. per cu. ft. at 760 Millimeters		Volume, cu. ft. per lb. of

4. KILN DRYING OF LUMBER*

The basic object in kiln drying of wood is to remove part of the moisture naturally present in it, which if allowed to remain ordinarily would interfere with its use. As soon as evaporation from the surface of the wood begins, a moisture gradient is established. The wood has been made drier on the surface than in the interior, and thereby a movement of moisture from the interior toward the surface has been started. As wood dries it shrinks. If the moisture gradient is too great, surface shrinkage will cause checks and other defects. Hence, drying conditions must be so controlled that the moisture gradient will not exceed that which is safe for the species and thickness of stock being dried. Such control is obtained by controlling temperature and humidity, and maintaining a positive ınd ample circulation of air. In comparison with drying problems where moisture renoval is the only factor, kiln drying of wood is a complex process, for if drying conditions temperature, humidity and circulation) are not properly controlled the wood may be njured and its value depreciated.

DRY KILNS may be divided into two general types: 1. The stationary or compartnent type, in which the entire charge of wood is subjected to approximately the same emperature and humidity conditions, which are varied as the drying progresses; 2. The rogressive type in which the charge is moved progressively from the entering end to he discharge end. The lowest temperatures and highest humidities prevail at the enterıg end and highest temperatures and lowest humidities at the discharge end.

Kilns also may be either of the *natural* or *forced circulation* type. In natural circulaon kilns, air movement is caused by differences in temperature; in forced circulation

* Contributed by L. V. Teesdale, Senior Engineer, U. S. Forest Products Laboratory, Madison, Wis.

kilns, by means of blowers, fans, steam jets, or water sprays. The method of disposing of evaporated moisture separates kiln types into two classes: 1. The *condenser kiln*, where the evaporated moisture may be removed by condensers in the kiln; 2. The *ventilated kiln*, where it is removed by passing out of the kiln some of the moist, hot air and admitting an equivalent amount of fresh air.

No general comparison of efficiency of kiln types can be made, as one high in evaporating efficiency may produce a product that is poorly dried and has a high degrade. Also some species may be dried rapidly under severe conditions with little degrade, whereas others must be dried very slowly under mild conditions to avoid damage.

WORK OF EVAPORATING MOISTURE.—The useful work accomplished in evaporating moisture from lumber may be considered as the latent heat of the evaporated moisture. The actual heat absorption is greater than this. About 30 B.t.u. per pound of dry wood are absorbed in separating the moisture from the wood when drying to zero moisture content. In practice, wood seldom is dried below 5% moisture content, and the amount of heat required is only about $^1/_3$ as much as when drying to zero moisture content. It is necessary, of course, to heat the wood from its initial temperature to the final temperature of the kiln. The total heat expenditure required for evaporation only may be considered as the sum of: 1. Latent heat of vaporization; 2. Heat required to overcome hygroscopic attraction of the wood; 3. Heat required to raise temperature of the material and its contained water to temperature of evaporation. To this must be added the amount of heat lost by radiation through walls, ceiling, and floor; heat required to raise temperature of air in the kiln; heat required for air entering in ventilated kilns or for reheating air in condensing kilns; and the amount of steam used in steam sprays for humidifying and for steaming or conditioning treatments. The amount of steam required to evaporate a known amount of moisture at given conditions readily can be calculated within reasonable limits.

For estimating purposes, in ventilated kilns an allowance for heating of about 5% of the gross volume of kiln space should be made for the fresh air that is admitted per minute to replace exhausted moist air. In condensing kilns, cooling effects of the condensers can be calculated. The steam used for humidification varies enormously and depends to a considerable degree on the construction of kilns and skill of the operator. In well-insulated kilns with tight doors and vapor resisting construction, vapor losses are low and a skillful operator can save steam by careful operation of the exhaust dampers. Steam used in steam sprays may vary from 25 to 100% of that used in heating coils.

CONDENSATION.—The condensation per square foot of radiation in dry kilns, assuming proper size of supply lines, drain lines and traps, depends on: 1. Air circulation across the coils; 2. Steam pressure; 3. Kiln temperature. In natural circulation kilns, about 1 sq. ft. of radiation is allowed for each 6 cu. ft. of kiln space above the rail level. At 5 lb. per sq. in. steam pressure, maximum kiln temperature is between 165 and 180° F. This temperature occurs when the lumber is practically dry. For higher temperatures, high-pressure steam is used. In one test kiln, the maximum condensation per sq. ft., at a temperature of 185° F. and 15 lb. per sq. in. steam pressure, was 0.17 lb. per sq. ft. per hr. Only about $^1/_3$ of this amount was used to maintain a temperature of 120° F. At 75 lb. per sq. in. steam pressure and 180° F., maximum condensation was 0.39 lb. per sq. ft. In kilns having forced circulation the amount of radiation required is reduced because the efficiency of the heating surface is increased. In external blower kilns the ratio of radiation to kiln space may be as low as 1 to 20.

Steam Required to Dry Lumber.—Table 4 shows the amount of steam required per 1000 board feet to dry various hardwoods from an air-dried condition, averaging 20% moisture content, to a final average moisture content of 5%, and for various softwoods from the green condition to a moisture content of 5%. The table is based on well-

Table 4.—Estimated Steam Consumption for 1-in. Lumber in Commercial Kilns

Species of Lumber	Condition	Time of Drying, days	Lb. of Water Evaporated per 1000 Board-ft.	Lb. of Steam per lb. of Water Evaporated	Lb. of Steam per 1000 Board-ft.
Oak.	Air dried	8–12	600	3 –4.5	1800–2700
Birch, Maple	Air dried	6– 8	575	2.5–4	1450–2350
Gum, red.	Air dried	7–10	450	2.5–4	1100–1800
Douglas fir	Green	3– 4	750	2 –2.75	1500–2050
Longleaf yellow pine.	Green	4	2000	2 –2.75	4000–5500
Shortleaf yellow pine.	Green	4	2550	2 –2.75	5100–7000
Ponderosa Pine.	Green	4	1800	2 –2.75	3600–5000

constructed compartment kilns, utilizing steam to control humidity, and thermostatic devices to regulate temperature and relative humidity. Where no means of controlling humidity is used, somewhat less steam is required and the quality of the product is lower. In poorly insulated kilns and kilns with leaky doors and walls, the steam consumption increases.

HEAT INSULATION

By P. Nicholls

General Reference.—Traite de la Chaleur, Peclet, translated in Steam Covered and Bare Pipe, by Paulding.

The practice of heat insulation may be divided into fields based on temperature ranges, which fix the types of materials best suited to the conditions. See Table 1.

Table 1.—General Division of Heat Insulation Fields

Field	Temperature Range	Applications	Materials Used
1	Below 32° F.	Refrigeration. Cold storage.	(a) Organic materials, wood, cork, vegetable and animal fibers. (b) Rock wool. (c) Air spaces. (d) Vacuum.
2	32° to 100° F.	Cold-water pipes. Building and room insulation.	
3	100° to 230° F.	Hot-water heating. Low-pressure steam heating. Hot-air heating.	(a) Air spaces. (b) Lower grade asbestos goods. (c) Molded materials. (d) Rock wool.
4	230° to 800° F.	High-pressure steam plants. Industrial processes. Heating ovens, etc.	(a) 85% magnesia (600° F.). (b) High grade asbestos goods. (c) Diatomaceous earth.
5	800° to 1800° F.	Furnace settings. Kilns. High-temperature stills, etc.	(a) Diatomaceous earth. (b) Clays.
6	Above 1800° F.	Firebrick and ceramic products field.	Firebrick and clays of various types.
7	3000° F. up. Fire protection only	Safes and vaults. Walls and buildings. Structural steel.	Varies with the temperature likely to occur.

1. COMMERCIAL INSULATORS

COMMERCIAL INSULATORS are classed as follows

1. Loose Vegetable or Animal Fibers, felted or molded, used only at low temperatures on refrigerating, cold-water or hot-water pipes or surfaces. Such insulators are wool and hair felt, and cork, by themselves or combined with asbestos or roofing papers or containers.

2. Asbestos Insulations made from loose fibers, molded to shape, and the surface hardened with a binder; or formed into a mattress between woven asbestos cloth; also formed into paper and built-up with intervening air spaces. Available for all moderate temperatures up to the limit of steam temperatures, and, when properly supported, for fire protection.

3. Mineral Wools, made by steam blasting blast furnace slag or fusible rocks, is used for stuffing spaces, and for forming into blocks with other materials. It chiefly is used for low-temperature conditions. It does not rot, but is brittle, easily shaken down, and should be supported by wires or by tufting.

4. Molded Powders with or without binders. The efficiency of such insulators depends largely on the proportion of entrained air in the molded product. The larger the percentage of voids, the greater will be its efficiency as an insulator. Those powders whose crystals have the smallest absolute conductivity and the best reflecting surface have the best efficiency.

Plaster of Paris, lime, gypsum and other materials have been used. Plaster of Paris, being an acid salt, corrodes metals; lime and gypsum naturally have low efficiency due to their high density when molded.

Molded cork scrap is used for low temperatures and refrigerating conditions.

Infusorial earth molds to a low apparent density, but unless used in block form, as cut from its bed, it has poor binding qualities and requires an artificial binder to give it

cohesion. Being an oxide of silica, it can, in its natural form, be used on the highest temperatures.

Basic hydrated carbonate of magnesia molds into shapes with 90% voids, and, due to interlocking of the minute crystals, possesses considerable inherent strength. Commercially, mixed with 10 to 15% of asbestos fiber to give added strength, it is known as *85% Magnesia*. It can be machined accurately to shape. A limiting maximum temperature of 600° F. generally is recommended.

Alumina and other refractory powders also are molded with binders. Light-weight refractories are made by mixing clay with carbonaceous materials which are burnt out during firing.

SYMBOLS FOR HEAT TRANSMISSION.—The following symbols are selected from Symbols for Heat and Thermodynamics approved by Am. Stds. Assoc., Feb., 1931. A = area; t = temperature, deg. F. or deg. C.; T = absolute temperature (deg. F. + 460) or (deg. C. + 273); L = length of path of heat, or thickness; Q = total quantity of heat transferred; τ = time; q = thermal transmission (heat transferred per unit of time); k = thermal conductivity (heat transfer per unit time per unit area, and per deg. per unit length); R = thermal resistance (deg. per unit of heat transfer per unit time); C = thermal conductance (heat transfer per unit time, per deg.); C_A = thermal conductance per unit area; h = surface coefficient of heat transfer (heat transferred per unit time per unit area per deg.); U = overall coefficient of heat transfer (heat transferred per unit time per unit area, per deg. overall).

UNITS EMPLOYED IN HEAT INSULATION.—American engineering practice has greatly confused data and published papers by the variety of units used, and care is necessary in using formulas and coefficients. The units most commonly employed are the square foot for area, the inch for thickness, the hour for time, and the Fahrenheit scale for temperature. In refrigeration work it is quite common to use the 24-hr. day for the time unit. Problems are simplified by using the foot for all length measurements.

In the square foot-inch-hour system, the conductivity coefficient is in B.t.u. per hour per square foot per degree F. per inch thickness. With the day as the unit of time the coefficient is 24 times this value, and with the foot as the unit of thickness, one-twelfth of the value.

Values sometimes are given in French or electrical units. The following factors will transform them to standard units.

1 calorie (small or gram-calorie) = 0.003968 B.t.u.

1 watt = 3.4128 B.t.u. per hour.

1 calorie per sq. centimeter per sec. = 13,280 B.t.u. per sq. ft. per hour.

Conductivity in French units = one calorie per second per sq. centimeter per centimeter thickness per degree C. = 2903 B.t.u. per hour per sq. ft. per inch thickness per degree F.

2. LAWS AND MATHEMATICS OF HEAT INSULATION

The fundamental mathematics and laws were developed by the French physicist Peclet and published in his Traité de la Chaleur in 1853. He also developed empirical laws from experiments with laboratory scale apparatus, embodying in his results values of fundamentals which made his formulas perfectly general.

The majority of practical applications involve the transfer of heat under constant conditions and do not include changes in the amount of heat absorbed in the insulation itself. Thus they are not affected by the specific heat of the insulation. Even though the conditions or temperature may be variable, the actual weight of insulation usually is not large and its total heat capacity will not greatly affect the results. Exceptions to this, under some conditions, may include buildings, underground and fireproofing problems.

Insulation calculations can be divided into two general types: 1. Where the surface temperatures on each side of the insulation are fixed, and the heat transfer is dependent on the heat conductivity of the material and the conductivity laws. 2. Where the heat must pass through materials and also be dissipated from or absorbed at one or more surfaces by radiation, absorption or contact with a fluid, usually air, only the temperatures at the extreme of the transfer being known. Assuming that a constant condition of heat flow has been reached, the mathematics depend on the fact that the total flow calculated at any section at right angles to the direction of the flow must be equal to the total flow at any other section.

HEAT FLOW THROUGH A MATERIAL WITH KNOWN SURFACE TEMPERATURES.—Let t_1 and t_2 = temperatures of the two surfaces; k = heat conductivity co-

efficient, assumed same for all temperatures; S = a shape factor. Then the heat units q passing through the body per unit time are expressed in general by:

$$q = S \times k \times (t_1 - t_2) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

If q = B.t.u. per hr., and k = B.t.u. per hr. per sq. ft. per deg. F. per inch thickness, the value of S, the shape factor, is:

For a Flat Block.—$S = A/L$; A = area, sq. ft., L = thickness, in.

For a Cylinder.—$S = 2\pi l/12 \log_e(r_2/r_1) = 0.227\, l/\log_{10}(r_2/r_1)$; r_1 and r_2 = inner and outer radii, in.; l = length of cylinder, ft.

For a Hollow Sphere.—$S = 4\pi\, r_1 r_2/144\,(r_2 - r_1) = 0.0875\, r_1 r_2/(r_2 - r_1)$; r_1 and r_2 = inner and outer radii.

Langmuir, Adams and Meekle (*Trans.* Am. Elect. Chem. Soc., vol. xxiv, 1913) give additional shape factors, one of which is:

For a Hollow Rectangular Construction with square edges and corners, and thickness of sides L, in.; S for each flat block side $= A/L$; A = inside area of side, sq. ft. S for each 0.54 $l/12$; l = length of inside edge, ft. S for each corner $= 0.15\,L/144$.

The complete S will be the sum of all such portions as are transmitting the heat; for a complete parallelopiped the whole S will be

$$S = \{2\,(l_1 l_2 + l_2 l_3 + l_3 l_1)/L\} + 0.45\,(l_1 + l_2 + l_3) + 0.008\,L \quad . \quad . \quad . \quad [2]$$

CONDUCTIVITY VARIABLE.—The formulas for heat transfer, given above, apply when conductivity is constant; this is sufficiently accurate for many purposes, but for greater accuracy the formula

$$\text{Heat transfer per unit time, } q = S\int_{t_2}^{t_1} f(t)\,dt \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

must be used, where $f(t)$ is true conductivity expressed as a function of temperature of the material. The true function would be expressed as a curve of conductivity against temperature. All insulating materials show an increase of conductivity with temperature; as a first approximation the curve can be taken as a straight line, so that $f(t) = a + bt$ expresses the conductivity, a and b being constants. The above general formula then reduces to $q = S\{a + b \times {}^1/_2\,(t_1 + t_2)\}\,(t_1 - t_2)$, which can be stated as

$$q = Sk_m(t_1 - t_2) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [4]$$

where k_m = conductivity for the mean temperature ${}^1/_2(t_1 + t_2)$. S has the same values as given above.

The derivation of the true conductivity curve is of interest mainly in research work. For a method of obtaining it and a graphical method of solving heat transmission problems with variable conductivity and surface transmission coefficients see P. Nicholls, *Trans.* A.S.H.V.E., vol. xxviii, 1922, p. 323–342; also G. B. Wilkes, *Jour.* Am. Ceramic Soc., vol. xvi, 1933, p. 129.

HEAT FLOW WITH COMBINED CONDUCTION AND SURFACE EFFECTS.—The rate of heat flow to or from a surface can be stated as: Heat per unit time passing through unit area of surface, $q = h(t_s - t_0)$, where t_s = surface temperature; t_0 = air temperature; h = coefficient of surface transmission in heat units per unit time per unit area per deg. F. temperature difference. The numerical values for h vary with temperature and conditions, and are treated more fully on p. 3-57.

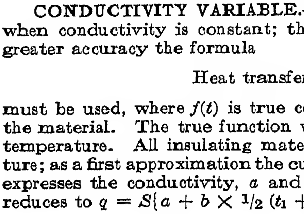

Fig. 1

With flow of heat under constant conditions the amount of heat passing through all sections at right angles to direction of flow must be the same. Problems are solved by equating these values. Practical problems usually are limited to the following:

Flat Parallel Plates.—Take the general example of a series of parallel plates of homogeneous materials with air spaces, coefficients and thicknesses as shown in **Fig. 1**; temperatures in deg. F., thickness L in inches, surface transmission coefficients h and air space conductance coefficients C_s in B.t.u. per hr. per sq. ft. per deg. F. temperature difference, and conductivity k in the same units per 1 in. thickness.

Let q = B.t.u. per hr. flowing through 1 sq. ft. of wall area. Then $q = h_1(t_0 - t_1) = (k_1/L_1)(t_1 - t'_1) = C_s(t'_1 - t_2) = (k_2/L_2)(t_2 - t'_2) = C'_s(t'_2 - t_3) = (k_3/L_3)(t_2 - t'_3) = h_2(t'_3 - t'_0)$.

If U = overall transmission, B.t.u. per hr. per sq. ft. per deg. F. difference between hot and cold air, these equations give

$$\frac{1}{(1/h_1) + (1/h_2) + (1/C_s) + (1/C'_s) + \qquad (L_3/k)_3}$$

It follows that $q = U(t_0 - t'_0)$. Values for the various surface temperatures are then successively found from equations: $t_1 = t_0 - (q_1/h_1)$; $t'_1 = t_1 - (qL_1/k_1)$; $t_2 = t'_1 - (h/s_1)$, etc. For a hot surface of temperature t_1, insulated with one thickness of L in. and with air temperature at t_0,

$$q = \{kh/(k + hL)\}(t_1 - t_0) \qquad [6]$$

Cylindrical Surfaces.—Let r_1 and r_2 = respectively inner and the outer radii of insulation, in.; t_1 and t_2 = respectively, temperature of inner and outer surfaces; t_0 = air temperature; q_1 = B.t.u. per hr. per ft. length. By equating heat transfer to surface loss,

$$\frac{1}{12} \times \frac{12 \cdot 2\pi r_2}{(1/h) + (r_2/k)\log_e(r_2/r_1)}(t_1 - t_0) = \frac{12 \cdot 0.523\, r_2 (t_1 - }{(1/h) + 2.3\,(r_2/k)} \qquad [8]$$

Having found the value of q_1, t_2 can be computed from one of the first equations.

If q = B.t.u. per sq. ft. of inner surface,

$$q \quad \frac{r_2}{r_1} \times \frac{1}{(1/h) + 2.3}$$

If insulation consists of two layers, the inner layer being of conductivity k_1 and radii r_1 and r_2, and the outer layer of conductivity k_2 and radii r_2 and r_3,

$$q_1 \text{ (per foot length)} = \frac{0.523\, r_3 (t_1 - t_0)}{(1/h) + 2.3\,(r_3/k_1)\log_{10}(r_2/r_1) + 2.3\,(r_3/k_2)\log_{10}(r_3/r_2)} \qquad [10]$$

These equations, both for flat surfaces and cylinders, assume that h and k are constants; for problems in the refrigerating and heating fields, values can be chosen and the equations solved directly. For the steam and refractories fields, in which variations of both h and k with temperature are large, assumptions must be made for the unknown temperatures, the corresponding values for the mean values of h and k selected, and the values for heat flow and temperatures computed. If temperatures do not correspond with those assumed, a new trial can be made. This process is rather tedious and for frequent computations graphic methods can be used. See L. B. McMillan, *Trans.* A.S.M.E., vol. xlviii, 1926, p. 1285; P. Nicholls, *Trans.* A.S.H.-V.E., vol. xxviii, 1922, p. 334.

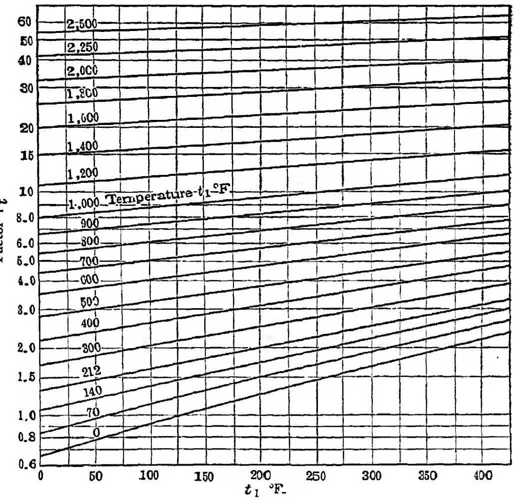

FIG. 2. Values of F_t

HEAT FLOW TO OR FROM A SURFACE.—The heat passing through 1 sq. ft. of surface can be expressed as $q = h\,(t_s - t_0)$ where t_s = temperature of surface, and t_0 = air temperature. Working values for surface coefficient h are available in each field of application of insulation for small temperature differences and for where surrounding objects are at the same temperature as the air. These values of h usually are for natural convection, but often include the effect of such average windage over the surface as is associated with the conditions. For more exact values, and for large temperature differences and for special conditions, the transfers by radiation and by convection must be computed.

The radiation q_r in B.t.u. per hr. per sq. ft. of surface is

$$q_r = 0.174\, e\,[\{(t_1 + 460)/100\}^4 - \{(t_2 + 460)/100\}^4] \qquad [11]$$

where t_1 = temperature deg. F. of surface considered, t_2 = temperature of the surrounding objects, e = total emissivity relative to a black body. The value to be used for e for

metallic surfaces may be uncertain, as it depends materially on polish, oxidization and cleanness. The following average values are sufficient for most insulation problems:

Surface	e	Surface	e
Aluminum or tin, polished..........	0.08	Steel and iron, commercial...	0.80 to 0.90
Aluminum and tin, varnished.......	.20	Non-metallic materials......	.92 to .96
Aluminum paint..................	.40	Lampblack................	.96
Oxide paints, all colors............	.94		

For parallel surfaces, large as compared with distance between them,

where e_1 and e_2 = emissivities of the two surfaces.

For most purposes labor in computation can be saved by expressing

$$q_r = eF_t\,(t_1 - t_2) \qquad [12]$$

where $$F_t = 0.174\,[\{(t_1 + 460)/100\}^4 - \{(t_2 + 460)/100\}^4] \div (t_1 - t_2) \qquad [13]$$

and obtaining F_t from Fig. 2, given by F. S. King.

The convection factor of the surface heat transfer depends on size and location of the surface; further, it may be natural or free convection, or forced convection due to windage. If q_c = transfer due to convection, B.t.u. per hr. per sq. ft.; $(t_1 - t_2)$ = difference between surface and air temperatures, deg. F.; an approximate formula for *free convection* for large vertical surfaces is

$$q_c = 0.22\,(t_1 - t_2)^{4/3} \qquad [14]$$

or per sq. ft. per deg. F., $$h_c = 0.22\,(t_1 - t_2)^{1/3} \qquad [15]$$

For horizontal surfaces the convection transfer is increased if a hot surface faces upwards or a cold surface downwards; it is decreased if a cold surface faces upwards or a hot surface downwards. The approximate increase or decrease of q_c can be taken as 30%. R. H. Heilman, *Trans.* A.S.M.E., FSP-51-41, pp. 294-5, gives complete diagrams and factors for obtaining both the radiation and convection surface of various shaped surfaces.

Windage greatly increases loss by convection. Experimental data for unconfined surfaces are meager, but it usually is not possible in practice to define the velocity of the wind, especially for large surfaces. From tests by F. B. Rowley on a 1 ft. square area, approximate values are given by the following:

Convection loss with wind = (convection loss in still air) $\times F \times V$, where V = velocity, and F = factor depending on the nature of the surface, F is greater as the surface is rough or as the wind can penetrate into the body. Values for F are:

Kind of Surface	F, with V in ft. per min.	F, with V in miles per hr.
Smooth (glass or paint)...........	0.33	0.0037
Moderately rough (brick).........	.54	.0061
Very rough (stucco).............	.80	.0090

TRANSFER OF HEAT ACROSS AIR SPACES.—An air space, rightly used, is an efficient insulator at low temperatures. The transfer of heat consists of direct radiation and air-transfer factors, *i.e.*, resultant of conduction and convection. The radiation factor depends on type of surface. It usually is assumed to be independent of width of

Table 2.—Average Value of Conductance for Vertical Air Spaces 24 in. High

(B.t.u. per sq. ft. per hr. per deg. F. temperature difference between surfaces)

Width of Space, in.	Air Transfer Coefficient. Conduction and Convection (without Radiation) for Given Width	Total Transmission Coefficient, C_g, for Given Width, B.t.u.					
		Between Building Materials		Between Bright Tin Surfaces		Between Building Materials and Bright Tin	
		At 32° F.	At 75° F.	At 32° F.	At 75° F.	At 32° F.	At 75° F.
1/8	1.36 B.t.u.	2.14	2.30	1.40	1.41	1.43	1.45
1/4	0.68	1.46	1.62	0.72	0.73	0.75	0.77
3/8	.45	1.23	1.39	.49	.50	.52	.54
1/2	.34	1.12	1.28	.38	.39	.41	.43
5/8	.28	1.06	1.22	.32	.33	.35	.37
3/4	.25	1.03	1.19	.29	.30	.32	.34
7/8	.23	1.01	1.17	.27	.29	.30	.32
1	.21	0.99	1.15	.25	.26	.28	.30
2	.18	.96	1.12	.22	.23	.25	.27
3	.19	.97	1.13	.23	.22	.26	.28

space; this is not strictly true, due to effect of the side of the spacers. Conduction is inversely proportional to width of space, until it becomes wide enough, at about $^3/_8$ in., to permit movement of air, when convection assists the transfer. Up to about $^3/_8$ in. width the total transfer is the same for vertical and horizontal spaces; above $^3/_8$ in., transfer with a horizontal space is smaller than for a vertical space if the hot face be on top, and greater if it be below. Efficiency of air spaces depends on their being sealed, so that no air can circulate through them. If circulation occurs, the insulating effect of the spaces is lost and it may actually increase the transfer.

The heat transfer, within close limits, varies with height of space and type of spacers used; for these reasons, the values obtained by investigators have differed. The method of test is to measure total transfer, compute radiation factor, and call the difference the air-transfer factor. In computing radiation (see p. 3–57), emissivity is $e_1e_2/(e_1 + e_2 - e_1e_2)$, where e_1 and e_2 are emissivity constants for the two inner surfaces of the space.

Table 2 gives values for C_S, conductance per hr. per sq. ft. per deg. F., using air-factor values determined by U. S. Bureau of Standards (Dickinson and Van Dusen, A.S.R.E., vol. iii, Sept., 1916). Emissivities of building materials are taken as 0.94, and of bright metal surfaces (tin or aluminum) as 0.08. Table 2 gives values for mean temperatures of 32° and 75° F., and an assumed temperature difference of 18° F. between faces; changes from 18° make little difference. The resulting radiation factors per deg. F. are:

	At 32° F.	At 75° F.
Building material to building material	0.78	0.94
Bright metal to bright metal	.04	.05
Building material to bright metal	.07	.09

For vertical air spaces 8 in. high, the following air transfer coefficients were found:

Width of space, in.	$^1/_8$	$^1/_4$			$^5/_8$	$^3/_4$	$^7/_8$	1.0
Coefficient	1.50	0.75	0.50	0.38	0.31	0.32	0.34	0.35

Adding the radiation coefficient gives total transmission coefficient for this height of space.

METAL ENCLOSED INSULATION.—If the metal is only an outside protecting sheet and does not pass into or through insulation it will not affect heat transfer computations. Insulating value will be improved in so far as the metal may seal the surface and prevent air circulation through the insulation, or penetration by wind or moisture.

In some applications, insulation is wholly or partly enclosed by metal, as in some panel constructions, on refrigerators and in safes. Such construction may materially decrease the average effectiveness of insulation. Exact computations for heat flow may be difficult but the analysis by M. S. Van Dusen (U. S. Bureau of Standards Research Paper 207) can be adapted to give sufficiently accurate results. The order of increase of heat flow which results from transfer by the metal sides is shown in Fig. 3, which is for a 40 × 40 in. panel completely enclosed by sheet iron. The panel is assumed to be exposed to air on both sides, and the insulation to have a value of $k = 0.3$ B.t.u. per hr. per sq. ft. per in. thickness per deg. F.

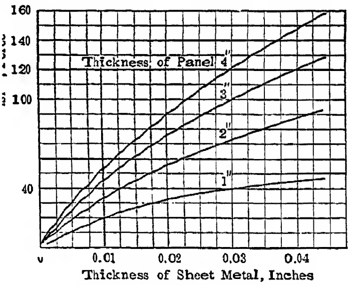

Fig. 3. Effect of Thickness of Metal on Heat Flow

The same bulletin treats the effects of bolts passing through insulation. Flow of heat through bolts increases greatly with increased area of head exposed to the air, or as it has direct thermal contact with a metal covering sheet. Hence the head should be insulated from the metal sheet. If the head is well insulated, or if there is no metal covering, heat flow is materially reduced, and by first principles is

$$\frac{0.0069\ (t_1 - t_2)}{(1/h_1 A_1) + (1/h_2 A_2) + (L/Ka)} \text{ B.t.u. per hr.} \qquad [16]$$

where t_1 and t_2 = air temperature on hot and cold sides, deg. F.; h_1 and h_2 = surface coefficients, B.t.u. per hr. per sq. ft.; A_1 and A_2 = exposed areas, sq. in., of bolt heads; a = area. sq. in., of bolt; K = thermal conductivity of the metal, B.t.u. per hr. per sq. ft., per in. thickness per deg. F. (steel = 300; copper = 2600). For a stud tapped into metal on one side $(1/h_2 A_2)$ will be zero. h_1 and h_2 may be taken as 1.5, or selected from Table 3.

3. INSULATION OF COLD SURFACES

The insulation of cold surfaces covers applications where transference of heat from hotter air must be prevented, and includes refrigerating, cold storage, ice houses and cold-water pipes. Its distinguishing feature is that the insulation is at a lower temperature than the air, so that moisture can condense in it, and thus lower its insulating efficiency. Air currents also tend to carry moisture from the hot side and condense it on the cold side.

CALCULATION OF HEAT TRANSMISSION.—The formulas given under Mathematics of Heat Insulation apply. Due to the small temperature range involved, variations with temperature of the coefficients of conductivity and the surface emissivity usually are neglected. These values usually have been determined at room temperatures, and will be smaller for lower temperatures so long as the materials remain dry. It is probable, however, that the greater amount of moisture present at the lower temperatures under service conditions more than offsets the decreased temperature gradient. Practical problems usually involve compound walls of such thickness that the surface coefficient has little influence on the result. The calculation of transmission through the walls does not include transfer of heat due to air leakage, infiltration, etc.

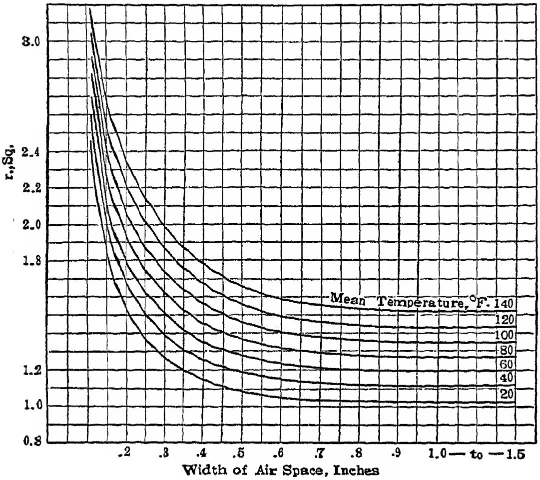

FIG. 4. Conductance of Air Spaces

The surface transfer coefficient will be lower on the cold than on the hot side. Table 3 gives average values for large areas for typical hot and cold temperatures.

AIR SPACES.—For air spaces in ordinary building construction, see Fig. 4 (F. B. Rowley, Univ. of Minn. *Bull.* No. 8). It shows the conductance C_s, B.t.u. per hr. per sq. ft. per deg. F. difference in temperature between surfaces. Heat flow values are larger than in Table 2, but will allow for leakage and rougher construction.

Increased application of air spaces as insulation has resulted from the availability of aluminum foil to provide surfaces of low emissivity, and the possibility of using a large number of sheets in a given thickness to reduce to a small value the transfer by radiation. Sheets as thin as 0.00028 in. are used and weight of the aluminum is low. Insulating value varies with the method used to separate sheets and maintain air spaces. Spacing strips produce the highest thermal resistance for a given space width; corrugated paper or asbestos and fibrous materials give good separation and some mechanical strength. Due to the thinness of the sheets there is little metallic conductance when spacing is

Table 3.—Average Values of Surface Coefficients *h*

(B.t.u. per hr. per sq. ft. per deg. F. difference)

Condition	Vertical Surface	Horizontal Surface: Hot Side Up or Cold Side Down	Horizontal Surface: Hot Side Down or Cold Side Up

Bright metal surface	0.8	1.1	0.5
COLD SIDE, 20° F.			
Building materials, still air	1.1	1.4	0.8

obtained by crumpling or embossing them, but the insulating value of crumpled sheets is inferior to corrugated structures. Insulating value depends on maintenance of the brightness of the foil; the surface does not tarnish easily under normal conditions. R. B. Mason (*Ind. and Eng. Chem.*, vol. xxv, 1933, p. 245) gives tests of various types of air spaces using aluminum foil in many forms; the above general conclusions are based on results of these tests.

THERMAL CONDUCTIVITIES OF BUILDING AND INSULATING MATERIALS.—Values found by investigators vary considerably, but as the only definition of the materials is by name and density, such differences can be expected. Even with the same density a material may have differences in physical qualities that will affect its conductivity, *e.g.*, temperature at which measurements are made, amount of contained moisture, hygroscopic qualities, and difficulties of making such tests. This applies in particular to such materials as brickwork and concrete. Standard insulating materials, especially if waterproofed, can be depended on to have a more constant value for the same density than can building materials. The true insulating value of a wall, particularly one ex-

posed to wind pressure, also will depend on its permeability to air. Apparent differences also may be due to confusion of terms. The heat resistance of the surface effect in some tables is included with that of the material; that is, the overall conductivity from air to air is given instead of the conductivity from surface to surface. The former decreases with the thickness of the test piece, whereas the true conductivity coefficient should be the same for any thickness of test sample.

The values given in Table 4 include most commercial insulations and are mainly taken from tests at the Bureau of Standards (Van Dusen, *Jour.* A.S.H.V.E., Oct., 1920). The tests were made by the hot plate method at a mean temperature of about 68° F.

Cork board has been largely used as a standard of reference but its thermal conductivity varies with its density and method of manufacture. According to tests by Wood and Grundhofer (Penna. State College, *Bull.* No. 30) the temperature gradient is 1% increase for every 4° F. Van Dusen gives curves of tests of cork board varying in density from 7 to 14 lb. per cu. ft., from which it can be deduced that $k = 0.161 + 0.011\,W + 0.00035\,T$, where k = conductivity coefficient, B.t.u. per hr. per sq. ft. per 1 in. thickness per deg. F.; W = specific weight, lb. per cu. ft.; t = mean temperature of the material, deg. F.

ECONOMIC THICKNESS OF INSULATION FOR REFRIGERATION.—The economic thickness for heat insulation is that thickness which will reduce to a minimum the sum of the expenses due to heat passed through it plus the expenses of preventing heat

For insulation applied to a flat surface the economic thickness is

$$X = 1.\sqrt{\frac{A(t_a - t)Fk}{B\{I + R + (100/Y) + 8.3S\}}} \qquad U \qquad [17]$$

where X = economic thickness of insulation, in.; k = thermal conductivity coefficient of insulation, B.t.u. per hr. per sq. ft. per in. thickness per deg. F. temp. difference; B = cost of insulation installed, dollars per sq. ft. per in. thickness; A = cost of one ton of refrigeration, dollars = (cost per B.t.u. × 288,000); I = percent interest allowed on investment; Y = life of insulation, years; R = yearly repair cost, as percent of investment in insulation; F = fraction of year room is in operation; t_a = average temperature, deg. F., of air on the wall side, during year or period of operation; t = cold air temperature, deg. F.; S = yearly value of 1 cu. ft. of space as taken up by insulation; U = overall thermal coefficient of heat transmission from air to air of the given thickness of wall, other than insulation, and including surface transmission coefficients of the wall and of the insulation exposed surface found in the usual way from $(1/U) = (1/h) + (1/h_w) + \Sigma(L/k_w)$, where h and h_w are surface coefficients, L is thickness of wall without insulation, in., and k_w is its coefficient.

Common values for the above factors are $I = 6\%$; $R = 2$ to 4%; $Y = 10$ to 20 years; $B = 5$ to 10 cents; $A = \$1.75$ for a small plant, to 90 cents for a large one. S usually can be neglected. Values for the other factors can be found in the tables. h and h_w each can be taken as 1.2.

For brine tank insulation t_a becomes room temperature, t is temperature of the brine, and S would be zero.

The same approximate thickness of insulation is recommended by the various manufacturers. The Armstrong Cork Co. gives the following:

Inside temp. of room, deg. F.	−20 to −5	−5 to +5	5 to 20	20 to 35	35 to 45	Over 45
Thickness of insulation	8	6	5	4	3	2

It is advantageous to make insulation thick enough to keep the temperature of the hotter side higher than the dew point of the air. This avoids condensation of moisture in the insulation, with consequent lowering of its insulation value and tendency to rot.

PREVENTION OF CONDENSATION ON COLD SURFACES.—Moisture will condense on a surface whose temperature is below that of the dew point of air in contact with it. In using insulation to increase the surface temperature, the first step is to fix

Table 5.—Temperature Difference between Dry Bulb and Wet Bulb for Various Relative Humidities, t_d, deg. F.

Relative Humidity, Percent	Air temperature, dry bulb, deg. F. 50	70	90	Relative Humidity, Percent	Air temperature, dry bulb, deg. F. 50	70	90
	Temperature Difference, deg. F.				Temperature Difference, deg. F.		
20	....	43	47	70	9.5	11	11.5
30	29	33.5	36.5	80	6.5	7	7
40	23	25.5	28	90	3.5	3.5	3.5
50	18.5	20	21.5	100	0	0	0
60	13.5	15	16				

the expected dry-bulb temperature of the air and its maximum relative humidity. Table 5 gives corresponding temperature drop t_d to dew point. If t_0 is temperature of the air, temperature of surface must be not less than $t_0 - t_d$.

If temperature of surface to be insulated will not be changed by applying insulation, as pipes carrying a cold liquid, the following formulas can be used for thickness of insulation: Let t_0 = air temperature, deg. F.; t_2 = temperature of surface to be insulated, deg. F.; t_d = drop to dew point, deg. F.; h_1 = surface coefficient, B.t.u. per hr. per sq. ft. per deg. F.; k = conductivity of insulation to be used, B.t.u. per hr. per sq. ft. per in. thickness, per deg. F.; L = thickness, in. Then

For flat surfaces. $$L = (k/h_1) \times \{(t_0 - t_2 - t_d)\}/t_d \qquad [18]$$

An average value for h_1 is 1.4; see Table 3 for more exact values.

For pipes the thickness is obtained from

$$r_2 \log_{10} r_2/r_1 = (k/2.3\, h_1) \times \{(t_0 - t_2 - t_d)/t_d\}. \qquad [19]$$

where r_1 = known radius of pipe, in.; r_2 = radius of outside insulation. A few trial values will give r_2.

For a wall exposed to air on both sides, let t_0 and t'_0 be temperatures of the air on hot and cold sides, respectively; let the wall without insulation have an overall coefficient from air to air of U, or a conductance from surface to surface of C_A, both in B.t.u. per hr. per sq. ft. per deg. F.; let h_1 and h_2 = surface coefficients on hot and cold sides respectively; k = conductivity of insulation; L = its thickness; all in same units as before. Then

$$k[\{(t_0 - \qquad \cdot 1/U], \text{ or } =. k[\{(t_0 - t'_0 - t_d)/h_1 t_d\} - \{(1/C_A) - (1/h_2)\}] \qquad [20]$$

4. INSULATION OF HOT SURFACES UP TO 800° F.

REQUIREMENTS FOR A GOOD COVERING. (Am. Rwy. Assoc. Circular No. S 111–147.)—1. Good non-conducting properties. 2. Fireproof. 3. Easily molded and of light weight. 4. Impervious to moisture. 5. Insoluble. 6. Unaffected by steam. 7. Non-corrosive. 8. Structurally strong to resist handling and vibration. 9. Sanitary and vermin proof.

STANDARD COMMERCIAL SIZES.—Block insulation is made in various sizes according to the material, but molded materials are standardized for 6 × 36 in., or 3 × 18 in., and of any thickness from 1/2 in. to 4 in.

Pipe covering is made in 36-in. lengths in sectional and segmental forms. Sectional forms are split longitudinally for ease of application, and used for all pipes up to 10 in. diam. and for larger sizes for laminated insulations. Molded covering for pipes over 10 in. diam. is supplied as segmental blocks about 6 in. wide.

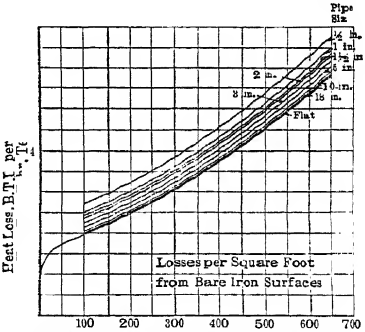

Fig. 5. Heat Loss from Bare Iron Pipe

HEAT LOSS FROM BARE HOT SURFACES.—For the principles and laws which fix the losses from any surface, see pages 3-55 to 3-59. The value of heat losses is best expressed as a given quantity of fuel wasted. It then can be translated into money values by multiplying by the unit value of fuel as fired. This applies to surfaces heated directly by the fire. If surfaces are heated by steam, hot water, or hot air, values so found must be divided by the efficiency of the boiler or other heat generator. If fuel other than coal is used, the following average conversion figures may be taken:

Fuel	Fuel oil	Natu	Producer gas	City gas
Heating value, B.t.u.	19,000 per lb.	1000 per cu. ft.	650 per cu. ft.	635 per cu. ft.
Quantity equivalent to 1 lb. coal of 13,000 B.t.u.	0.69 lb.	13 cu. ft.	20 cu. ft.	21 cu. ft.

The general laws, which were based on tests with hot surface temperatures of 150° F, and lower, developed by Peclet, were commonly used. The Mellon Institute (Heilman,

Mech. Engg., May, 1922) determined the heat loss of horizontal iron pipes of various sizes, and the surface transmission coefficients found are shown in Fig. 5. These agree closely with Peclet's laws up to about 400° F. temperature difference, after which the values found are lower. The flat surface extension below 100° F. has been added, based on Peclet's laws. The falling off of the curve is due to the convection losses being lower. This was confirmed by the experiments of Langmuir. The values are based on an air temperature of 70° F.

HEAT LOSSES FROM FLAT IRON SURFACES.—Average losses from flat vertical surfaces derived in the same way as for pipes are given in Table 6. They also are safe for use for building materials, such as brick. The actual loss will vary with height, convection loss increasing with decrease in height below 24 in. in the same manner as with

pipes. In so far as free convection is prevented the loss will be decreased. The loss from exposed horizontal surfaces facing upwards will be greater, due to an increase of about 10% in the convection factor (Langmuir) or approximately the following percentage increase over the figures given in Table 6.

Temp. difference, deg. F.....	50	100	200	300	400	500	600
Percent increase.............	4.0	4.4	4.7	4	3.5	3	2

When the hot surface faced downward the loss was found to be less and to depend on the ability of the hot air to escape. The decrease from the values given in Table 6 may run to five to eight times the above percentages when convection currents are prevented.

HEAT LOSSES FROM BARE IRON PIPES.—Table 7 gives values of heat losses for common steam temperatures. The values are for horizontal pipes. Those for vertical pipes would be somewhat smaller. The pipes are presumed to have their natural oxidized finish.

STEAM PIPE TEMPERATURES.—Losses from hot surfaces are dependent only on surface temperature, and not on the method of heating or the fluid inside. The surface temperature may, however, be less than that of the fluid, and in general it will be. For saturated steam the difference is very small if the steam is free from air and if the pipe is well drained. With superheated steam, there will be an appreciable drop, the amount depending on size of pipe, velocity of steam and rate of loss. The drop will increase with the surface loss, and thus will be more for bare than for insulated pipe. The actual relationship is complicated, as the average temperature of superheated steam in a pipe decreases along its length, due to the loss of heat which occurs from the pipe. For ordinary insulation purposes it is sufficient to take the surface temperature as that of the nominal temperature of the superheated steam, less 20% of the superheat for bare, and less 5% for insulated surfaces (see R. Poensgen, *Zeit.* V.D.I., lx, p. 27). For long-distance transmission with superheat, the total heat loss would have to be approximated to find the drop in steam temperature.

HEAT TRANSFER COMPUTATIONS.—The fundamental formulas given under Mathematics of Heat Insulation are used, but due to the large temperature ranges, k and h (conductivity and surface transmission coefficients) cannot be considered constant except for approximate values. It is customary for manufacturers to publish conductivities at mean temperatures, the meaning of which is described under Variable Conductivities, p. 3–56. Unless a graphical method is used, computation for heat flow for a given insulation must be by trial, in which a surface temperature of the air side of the insulation is assumed. If conductivity at the mean temperature of the insulation is used, rate of heat flow should equal computed air loss; if it does not, another surface temperature is tried. Values in Table 7 can be used as a guide.

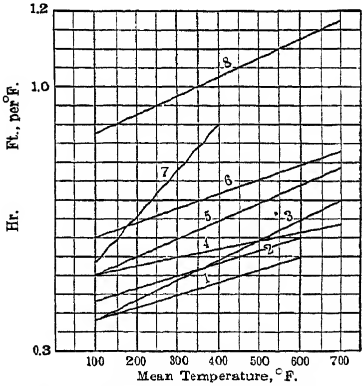

FIG. 6. Mean Conductivity of Insulation

1. Asbestos pape and sponge (sponge felt, multi-ply); 2. 85% Magnesia; 3. Rock wool; 4. High-temp. compound (High-temp., super X); 5. Molded diatomaceous earth (Non-Pareil); 6. Asbestos with hard coal (Thermalite); 7. Asbestos air cell. 8. Asbestos molded with silicate of soda (Firefelt)

For Canvas Coverings with natural or painted finish (other than aluminum paint) value of surface coefficient h can be taken as $(1.2 + 0.01\ T_d)$ for 4 in. outside diam.; $(1.3 + 0.01\ T_d)$ for 4 to 8 in.; $(1.4 + 0.01\ T_d)$ for larger sizes, where $T_d =$ difference of temperature between surface of covering and the air. Aluminum paint will reduce this value about 30%.

Many types of insulation are on the market. Values for mean conductivity usually are given by manufacturers. Fig. 6 gives average values for a few standard types.

HEAT TRANSFERENCE TABLES.—Average calculated values for the heat passing through high-grade insulating coverings for all pipe sizes and for flat surfaces are given in Tables 8 and 9. Intermediate temperatures can be interpolated. The values are actually for 85% Magnesia but they are sufficiently close to those of other high-class insulations such as felted asbestos, or Nonpareil infusorial coverings to be used for them. Naturally, all commercial insulations show some variations for different samples, depending mainly on the specific density of the material.

The tables are calculated for commercial thicknesses of the 1907 Manufacturers' List. Conductivity coefficients used are as follows, temperatures being actual and not temperature differences:

Temperature, deg. F......	100	200	300	400	500	600	700
Conductivity.............	0.5	0.52	0.55	0.583	0.62	0.66	0.71

The value of k used is approximately $k = 1.35 + 0.01(t_2 - t_0)$.

ECONOMIC THICKNESS OF INSULATION.—Computations for economic thickness of insulation for pipes involve trial and error or graphical methods. Since they include uncertainties of predictions for value of the heat and life of insulation, great accuracy usually is not required. Approximate values can be obtained from Fig. 7, which was originated by L. B. McMillan. The chief uncertainty is the choice of value for mean conductivity, but temperature drop from the surface of insulation to air as given in Table 7 can be used as a guide to surface temperature of insulation.

UNDERGROUND INSULATION OF STEAM MAINS.—Exact calculations of loss of heat from pipes buried in the ground includes the heat absorption power of the soil, and its change of temperature. It also is affected by intermittent operation, the seasons, and the rainfall. Prof. J. Allen (*Jour.* A.S.H.V.E., May, 1920) covers the mathematics of buried pipes on the assumption that constant conditions have been reached, and shows that: 1. Heat lost per sq. ft. of pipe decreases with increasing diameter. 2. As the soil acts as an insulator, the advantages of an increase in thickness of insulation is not as great as for a pipe in air. 3. Little increase in insulating effect is gained by burying pipe more than 2 ft. deep. 4. Nature and dampness of soil largely will affect results independent of the special covering.

The general systems of underground steam pipes and the insulation associated with them are: 1. The insulated pipe is buried in the ground without additional construction other than loose stone drainage under the pipe if soil is very damp. The pipe is insulated as for overhead construction, covered with overlapping layers of tar paper sealed with hot asphalt. Insulation must be able to sustain weight of the soil. 2. Conduit systems, where pressure of the soil is taken by the conduit; such systems always have efficient drainage. The conduit is laid in rubble, which, if necessary, contains drainage pipes. Some types of conduits are: *a.* Impregnated wood ducts; pipes are insulated in the regular manner, supported in center of the duct, and thus have the additional insulating value of the air space; *b.*

Rectangular ducts built in a trench; ducts may be all concrete or concrete top and bottom with tile or brick sides. See Fig. 8. *c.* Split molded tile conduit with sealed joints. Fig. 9 shows various types. 3. Man size tunnels; method of insulation is similar to that of overhead construction, but there may be some gain if air temperature is higher than normal.

How much heat loss is reduced by burial of pipe or conduit depends on dampness of the soil, and on whether dampness is maintained and heat carried away by water perco-

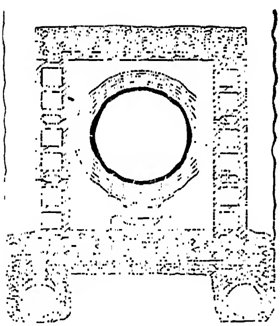

FIG. 8. Rectangular Pipe Duct

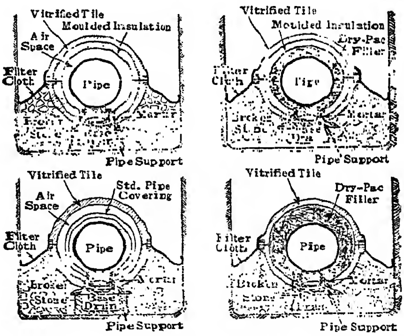

FIG. 9. Methods of Insulating Buried Pipe

lating through the soil. The most important factor is to keep the insulation dry, whether moisture comes from the soil or steam leaks. Insulation should not be damaged by wetting and subsequent drying; water vapor produced by drying should be able to escape. If loose packing is used, it should not sag if wetted, and should be able to stand vibration if buried below traffic lanes. Insulation with low water-absorbing properties is desirable. The effect on insulation of movement of the pipe, due to expansion, should be considered.

Exact computations for heat loss must depend on assumptions for dryness and gradual heating up of surrounding conduits and soil. The thickness of insulation for suspension in air sometimes is computed, and its thickness then decreased 1/2 in.

Insulation Efficiency as used for underground pipes is determined as follows: Compute the heat loss of the same length of bare pipe at the same steam temperature, suspended in air; subtract the actual loss as measured by test; the difference, divided by bare pipe loss, multiplied by 100 is the efficiency.

5. HIGH-TEMPERATURE AND FURNACE WALL INSULATION

The high-temperature field includes conditions where the temperature is greater than, say, 1000° F., as in furnaces, boiler walls, kilns, stills, ovens, etc. It involves insulation of surfaces at high temperature, or deals with heat transfer through refractories with or without additional better heat-insulation material. A good refractory material is essentially strong and dense, and consequently is a good conductor of heat; to prevent excessive heat loss it must be made very thick, or a material of lower conductivity must be built into the wall, or placed on the cool side of the refractory. The large area of the outer

surfaces of furnaces involves a great total heat loss, with consequent waste of fuel, uneven temperatures, undue heating of surroundings and conduction of heat to floors.

The high-temperature field of heat insulation has received much attention in recent years (1935), both in design of structures and in developing insulations to withstand higher temperatures without deterioration, and refractories of lower heat conductivity. In addition, industrial process developments, particularly in the oil industry, have made it profitable to prevent losses, because of the higher value of heat or because of more uniform operation resulting from decreased heat loss.

CALCULATION OF HEAT TRANSFER.—The formulas given under Mathematics of Heat Insulation apply. Due to the large ranges in temperature, the change of conductivity with temperature cannot be neglected in exact computations. Great accuracy in computation, however, usually is unwarranted for furnaces unless there is full knowledge of temperatures on the hot side of the walls. These temperatures often are not closely predictable, vary over the area of the wall, and are not constant. Other factors affect

heat flow and may affect materially the accuracy of computed, as compared with actual, heat flow. These are: *a*. Uncertainty of conductivity of refractories. *b*. Effect of slag erosion, slag accumulations, or contamination of the refractory by slag. *c*. Deterioration of wall structure. In many instances, however, exact computation is warranted.

VALUES OF THE SURFACE COEFFICIENT.—Relatively few data exist from which to derive a value of h for surfaces exposed to flame. It usually is sufficient for most purposes to base computations on an assumed temperature of the hot surface. At furnace temperatures, the main part of the transfer is by radiation; for a full treatment of this subject see W. H. McAdams, Heat Transmission, chap. iii.

Table 10 gives values of h for the surface of the wall exposed to air. Values are for vertical walls of iron, brick or other building materials. Table 10 also gives the B.t.u. dissipated per hr., *i.e.*, $h \times$ temperature difference. The total loss in fuel per sq. ft. per year of 300 days (7200 hr.) with coal of 13,000 B.t.u. per lb. is shown. This is the fuel loss with direct-fire heat. If it is indirect, as in steam heat, the equivalent pounds of coal loss is increased by dividing the values by furnace efficiency.

THERMAL CONDUCTIVITIES OF REFRACTORIES.—Values for thermal conductivities of refractories are not well defined, because of variations in properties of products bearing the same name, and because experimental work is difficult and incomplete. Values obtained by some investigators show that the change of conductivity with temperature does not follow the straight line law $k = a + bt$, and therefore mean conductivity (see Variable Conductivity, p. 3–56) will depend on the range of temperature covered. However, the mean method is more convenient and values for the true conductivities are so uncertain that values in Table 11 are on the mean conductivity basis. They are from experiments and compilations by F. H. Norton. No claim is made that these exact values are true for all bricks of the same name.

For approximate calculations in heat insulation problems for average furnace conditions, the following mean conductivity values for k can be used in B.t.u. per hr. per sq. ft. per deg. F. per in. thickness.

Kind of Brick..............	Common	Fire	Silica	Magnesia
k.....................	6	10	12	30

THERMAL CONDUCTIVITIES OF INSULATION.—If insulation is placed outside of a refractory structure the maximum temperature to which it will be subjected may fall within the range of materials used in the steam temperature field; for conductivities of such materials, see p. 3–65. Table 12 gives conductivities and other data on materials

able to stand higher temperatures, which values were obtained at the Mellon Institute by R. H. Heilman. Results obtained by different investigators lack agreement, even for such homogeneous materials. This statement applies particularly to conductivities at higher temperatures, but the values of Table 12 have been determined by the same method and are true relatively. Maximum temperatures are those recommended by the manufacturers. The materials listed are supplied in standard 9 in. size, and some also in blocks or special shapes.

TYPICAL WALLS.—Table 13 gives heat flow and heat content of typical walls. Construction is assumed to be firebrick and Sil-O-Cel insulation. Relative changes in values with other materials can be determined from Tables 11 and 12, but these will not be great.

APPLICATION OF INSULATION.—The decision of whether it will pay to apply insulation to a furnace cannot be made on the economic basis alone. It is an engineering problem for each class of furnace and the conditions of its use, and in particular whether the use is continuous or intermittent. Following are some main considerations and precautions necessary: *a.* Inclusion of insulation must not risk weakening the structure. *b.* Thickness of insulation, and its location in the walls, must be such that maximum temperature in insulation will not exceed the limiting temperature specified for it; it is important that this maximum temperature be that which will obtain under the most severe conditions of operation, and not the average value. *c.* Addition of insulation usually will not materially increase the temperature of the hot face of the refractory, but it will decrease drop in temperature through it, *i.e.*, increase its average temperature. If furnace temperature is so high that refractory temperature is near the melting point, or where rapid erosion by slagging will occur, it is necessary to consider whether or not the life of the refractory may be shortened. *d.* Insulation exposed to weather should be well waterproofed, particularly for furnaces which may be shut down in winter, when insulation may be damaged by freezing of moisture in it. *e.* If a furnace operates intermittently, the effect of heat stored in the walls is important. If it must be cooled between runs, it is desirable that insulation be as near the hot side as allowable; if temperature is to be maintained between runs, insulation can be placed on the outside.

THERMODYNAMICS

Revised by A. G. Christie

1. THERMODYNAMIC LAWS

THERMODYNAMICS, the science which deals with the transformations of energy, is useful in studies of steam, gas and air engines, steam and gas turbines, air and gas compressors, refrigerating machines, etc. The works of Goodenough, Lucke, Barnard, Ellenwood and Hirshfeld, Kiefer and Stuart, Ennis, Ewing, Dalby, Ripper, and Emswiler are among the standard textbooks on Thermodynamics.

ENERGY may be defined as the capacity for producing an effect. Energy may exist in stored forms as the kinetic energy of a moving body, the potential energy of an elevated or elastically strained body, the internal molecular energy in a hot substance, the chemical energy in fuel or a charged storage battery, etc.; it may be in transition as work due to the action of a superior force, as heat transfer due to a superior temperature, or as electrical energy due to a superior electrical potential.

Kinetic Energy is possessed by a body when work can be done as a result of a change in velocity. Thus if a body of weight w has a velocity of V_a, its kinetic energy $= wV_a^2/2g$. If the velocity is changed to V_b in the process of doing work, then the work done $W = w\,(V_a^2 - V_b^2)/2g$.

Internal or Intrinsic Energy is the energy stored in a body above some datum state, due to its molecular movements and arrangements or other internal effects. This quantity will be denoted by U.

WORK is the action of a force in displacing a resistance through a distance. It is measured by the product of the force multiplied by the distance moved in the direction of the force. (Barnard, Ellenwood, and Hirshfeld).

UNITS OF ENERGY.—The conventional units of energy are derived from simple phenomena associated with the transition of energy. They are:

a. **The Foot-pound** (ft.-lb.), which is the amount of energy (exhibited as work) associated with the action of a force of 1 lb. applied through a distance of 1 ft.

b. **The British Thermal Unit** (B.t.u.), which is 1/180 of the energy supply required to raise the temperature of a pound mass of pure water from 32° F. to 212° F. at a constant atmospheric pressure of 14.696 lb. per sq. in. absolute.

c. **The Horsepower-hour** (Hp.-hr.), which is the transition of energy at the rate of 33,000 ft.-lb. per min., or 550 ft.-lb. per sec.

d. **The Kilowatt-hour** (kw.-hr.), which is the transition of energy at the rate of 1000 watts per hour or 1.341 Hp.-hr., or 44,253 ft.-lb. per minute.

The relative magnitudes of the several units are: 1 B.t.u. = 778 ft.-lb.; 1 Hp.-hr. = 2543 B.t.u.; 1 kw.-hr. = 3411.5 B.t.u. Values for the Hp.-hr. and kw.-hr. are based on the recommendations of the International Steam Tables Conference, 1929.

THE ENTHALPY (formerly called *Total Heat* or *Heat Content*) of a unit weight (1 lb.) of a substance is the sum of its internal energy U, in B.t.u. per lb., above some datum and the product, Pv_s, of its pressure and volume at the given state. Enthalpy in B.t.u. per lb. $= h = U + A\,P\,v_s$, where $A = 1/778.6$; P = absolute pressure, lb. per sq. ft.; and v_s = specific volume of 1 lb. in cu. ft.

THE FIRST LAW OF THERMODYNAMICS is simply a statement of the principle of the conservation of energy, namely, that energy may exist in many varied and interchangeable forms but may not be quantitatively destroyed or created.

ENERGY EQUATIONS.—If a unit weight of 1 lb. of a substance flowing steadily through a heat engine passes from initial state 1 to final state 2, the energy equation covering the general case is $E_m = h_1 - h_2 + Q_h + \dfrac{(V_1^2 - V_2^2)}{778.6 \times 2g} + \dfrac{(Z_1 - Z_2)}{}$

where E_m = amount of mechanical energy furnished by the machine, B.t.u. per lb.; h_1 and h_2 = enthalpy (or total heat) of 1 lb. of the substance at state 1 and state 2 respectively; V_1 and V_2 = velocities of substance, ft. per sec., passing the sections at states 1 and 2, respectively; Z_1 and Z_2 = elevations of sections at states 1 and 2, respectively, above datum, measured in ft., of the substance; g = gravity = 32.16; Q_c = loss of heat by conduction and radiation between states 1 and 2, B.t.u. per lb. of the working substance. Q_h = heat added to (+) or taken from (−) working substance in the heat engine, as by jackets or by cooling water, B.t.u. per lb. of working substance.

In an engine or turbine without jackets $Q_h = 0$, if $V_1 = V_2$, and $Z_1 = Z_2$; then $E_m = h_1 - h_2 - Q_c$.

In a perfectly heat insulated engine $Q_c = 0$ and the work done, $E_m = h_1 - h_2$.

ABSOLUTE TEMPERATURE.—Temperatures are measured in degrees Fahrenheit. Absolute zero is at $-459.6°$ F. Absolute temperature $= t°$ F. $+ 459.6$, where $t =$ observed temperature on a thermometer which has 180 divisions between the freezing temperature and the boiling point of pure water.

THE SECOND LAW OF THERMODYNAMICS has been stated in a variety of ways by different writers. This law embodies the idea of availability of energy and of degradation of energy, or the tendency of high-grade energy to degenerate into low-grade energy. The following are selected statements of this law:

It is impossible for a self-acting machine unaided by any external agency to transfer heat from one body to another at a higher temperature (Clausius).

It is impossible by means of inanimate material agency to derive mechanical effect from any portion of matter by cooling it below the temperature of surrounding objects (Kelvin).

No machine, actual or ideal, can both completely and continuously transform heat into mechanical energy (Barnard, Ellenwood and Hirshfeld).

No change in a system of bodies that can take place of itself, can increase the available energy of a system (Goodenough).

If all the heat absorbed be at one temperature, and that rejected be at one lower temperature, then will the heat which is transmuted into work be to the entire heat absorbed in the same ratio as the difference between the absolute temperature of the source and refrigerator is to the absolute temperature of the source. In other words, the second law is an expression for the efficiency of the perfect elementary engine (Wood).

The expression $\frac{Q_1 - Q_2}{Q_1} = \frac{T_1 - T_2}{T_1}$ thus may be called a symbolical or algebraic enunciation of the second law—which law limits efficiency of heat engines, and which does not depend on the nature of the working medium employed (Trowbridge). Q_1 and $T_1 =$ quantity and absolute temperature of heat received; Q_2 and $T_2 =$ quantity and absolute temperature of heat rejected.

The expression $(T_1 - T_2)/T_1$ represents the efficiency of a perfect heat engine cycle which receives all its heat at the absolute temperature T_1, and rejects heat at the temperature T_2, converting into work the difference between the quantity received and rejected.

A conclusion that is of outstanding engineering significance derived from the Second Law is that the *maximum* work output obtainable from an engine equals the change of enthalpy for an adiabatic isentropic expansion of the fluid flowing through the engine.

Example.—What is the efficiency of a perfect heat engine cycle which receives heat at 428.3° F. (temperature of steam at 400 lb. gage pressure) and rejects heat at 79° F. (temperature of a condenser at 29 in. vacuum or 1 in. absolute pressure)?

$$\{(428.3 + 459.6) - (79 + 459.6)\}/(428.3 + 459.6) = 39.34\%$$

This efficiency never can be attained in an actual engine or turbine, since the energy available between the condition of the steam entering and the pressure at which it leaves is not all converted into work. Some of this available energy is dissipated in conduction and radiation, leakage, reheating effects, and in the case of reciprocating engines, in cylinder condensation and re-evaporation, all of which tend to reduce efficiency. The quantity $Q_1(T_1 - T_2)/T_1$ is available to do work in a perfect engine. The amount Q_1T_2/T_1 is unavailable under the given conditions.

REVERSIBILITY.—A process is said to be *reversible* when the following conditions are fulfilled: *a.* When the direction of the process is reversed, the system taking part in the process can assume in inverse order the states traversed in the direct process. *b.* The external actions are the same for the direct and reversed processes. *c.* Not only the system undergoing the change but all connected systems can be restored to initial conditions (Goodenough).

Any process that fails to meet these requirements is an *irreversible process*. Three irreversible processes are of frequent occurrence: *a.* The direct conversion of work into heat through the agency of friction. *b.* The conduction of heat from a body at temperature t_1 to another at temperature t_2. *c.* The throttling or wire-drawing of a fluid in flowing through an orifice from a region of higher to a region of lower pressure.

A PRESSURE-VOLUME DIAGRAM is one whose ordinates are pressures and abscissas are volumes. If a line is drawn on this diagram which represents the successive changes of state of the substance in passing from state a to state b, the area under this line represents the work done on or by the substance during this change if the state change be mechanically reversible, in that no mechanical or fluid friction or turbulence occurs.

ENTROPY may be considered as the length of a diagram, the area of which represents a quantity of energy added or removed, and the height at any point represents absolute temperature. The gain in entropy Δs for any reversible path between any two temperatures T_1 and T_2 is $\Delta s = \int_{T_1}^{T_2} \frac{dQ}{T}$. For constant temperature changes, entropy change $\Delta s = Q/T$, where $Q =$ energy added, B.t.u., per lb., and $T =$ absolute temperature, deg. F. For constant volume changes of gases remote from condensation conditions $\Delta s = c_v \log_e T_2/T_1$, and for constant pressure changes $\Delta s = c_p \log_e T_2/T_1$, where c_v and

c_p are the specific heats, B.t.u. per lb., at constant volume and pressure. T_1 and T_2 are the initial and final absolute temperatures, deg. F. Where energy is added to water at constant pressure to raise it to the boiling point, or energy is added to steam at constant pressure to superheat it, the mean specific heat at constant pressure over the given temperature range must be used.

The Temperature-entropy Diagram is one in which the ordinate or vertical line represents absolute temperature and the abscissa or horizontal line measures the change in entropy. Entropy usually is measured above 32° F. in steam tables and on these diagrams. Horizontal lines on temperature-entropy diagrams are isothermals, while vertical lines are reversible adiabatics. The employment of entropy often will simplify thermodynamic calculations by using algebraic or graphical methods instead of calculus.

An Isothermal Change is one during which the temperature of the working substance remains constant.

An Adiabatic is any process in which no heat is transferred to or from the working substance from any outside source.

A Reversible Adiabatic takes place at constant entropy, *i.e.*, an *Isentropic*. In this case no heat from an outside source is added to the working substance, nor is any heat lost to an outside body and no friction exists, either mechanical or fluid. The reversible adiabatics make available the greatest amount of energy for doing external work, and are the standards or reference in the Rankine cycle. In steam turbine calculations the ideal heat drop $(h_1 - h_2)$ per lb. of steam, and consequent maximum work, is found from an isentropic adiabatic expansion.

An Irreversible Adiabatic is a process in which there is no transfer of heat from the outside to the working substances, but in which more or less of the ideally available energy of the working substance fails to be obtained as work output, due to the presence of fluid or mechanical friction.

MOLLIER DIAGRAM.—Besides the temperature-entropy diagram, another, known as the Mollier Diagram, is widely used for vapors and gases. This diagram is plotted with enthalpy h as ordinate and entropy s as abscissa. (See p. 5–19 for a diagram for steam.) Vertical lines of constant entropy represent reversible adiabatic changes. Pressure, temperature, and volume lines can be placed on such a chart.

2. PROPERTIES OF GASES

Notation.—P = absolute pressure, lb. per sq. ft.; v = volume, cu. ft.; P_0, v_0 = pressure and volume at 32° F.; t = observed temperature, deg. F.; T = absolute temperature = $459.6 + t°$ F.; c_p = specific heat per lb. at constant pressure, B.t.u.; c_v = specific heat per lb. at constant volume, B.t.u.; K_p = ft.-lb. of energy equivalent to specific heat at constant pressure = $778.6\, c_p$; K_v = ft.-lb. of energy equivalent to specific heat at constant volume = $778.6\, c_v$; R = a constant for a given gas = $(K_p - K_v)$; $\gamma = c_p/c_v$; r = ratio of isothermal expansion or compression = P_1/P_2 or v_2/v_1 for expansion when $P_1 v_1 = P_2 v_2$ and P_1 is the higher pressure; w = lb. of working substance.

Boyle's or Mariotte's Law.—The volume of a perfect gas at constant temperature varies inversely as the absolute pressure. Thus, if P_1 = absolute pressure at volume v_1, and P_2 = absolute pressure at volume v_2, then with T = a constant, $v_2/v_1 = P_1/P_2$, or $P_1 v_1 = P_2 v_2 = C$, where C = a constant.

This law has been found by experiment to be very nearly true for all gases. For instance, air compressed to 75 atmospheres has a volume 2% less than that computed by Boyle's law, but this is the greatest divergence that is found below 160 atmospheres.

Charles's Law.—The volume of a perfect gas at constant pressure is proportional to its absolute temperature. If v_0 be the volume of gas at 32° F., and v_1 the volume at any other temperature t_1, then $v_1 = v_0 \left(\frac{t_1 + 459.6}{491.6}\right)$; v_1 $\quad \frac{32}{1.6}\Big)$;

$$v_1 \quad \{1 + 0.002034\,(t_1 - 32)\}v_0.$$

If the absolute pressure also changes from P_0 to P_1, $v_1 = \frac{P_0}{P_1}\left(\frac{t_1 + 459.6}{491.6}\right)$

The Characteristic Equation of Gases is a combination of the two preceding laws, $Pv = wRT$, where R is a constant for a given gas or mixture of gases. (See Table 3.)

Avagadro's Law.—Equal volumes of all gases under the same conditions of pressure and temperature contain the same number of molecules. Hence the densities of gases at the same pressure and temperature are proportional to their molecular weights.

THE MOL is that quantity of a gas at a given pressure and temperature whose weight in pounds equals its molecular weight. It is evident from Avagadro's Law that the vol-

ume of a mol is constant for all gases at any given pressure and temperature. At 32° F. and atmospheric pressure of 14.7 lb. per sq. in. the volume of a mol of gas = 358.7 cu. ft. This volume of any gas weighs m lb. where m = the molecular weight. (See Table 3 for molecular weights.)

The volume of 1 lb. of any gas at atmospheric pressure and 32° F. = $358.7/m$ cu. ft. The weight of 1 cu. ft. of any gas at 32° F. and atmospheric pressure = $m/358.7$ lb.

Universal Gas Constant.—Let v in the characteristic equation of a gas = 1 mol at atmospheric pressure and 32° F. On solving

$$mR = Pv/T = (2116.4 \times 358.7)/(459.6 + 32) = 1544,$$

which is called the *Universal Gas Constant*. For any gas, $R = 1554/m$. Also

$$R/778.6 = 1544/778.6\,m = 1.985/m = c_p - c_v;\ \text{or}\ R = 778.6\,(c_p - c_v) = (K_p - K_c),$$

the difference between the specific heats of 1 lb. of gas at constant pressure and at constant volume, expressed in ft.-lb.

THE SPECIFIC HEAT OF GASES.—The instantaneous molal specific heats of gases at constant pressure, *i.e.*, the specific heat of m lb. of gas at a given temperature when raised 1° F., where m = molecular weight, as given in Combustion, 3d edition (Amer. Gas Assoc., 1932, p. 59), and based on the Eastman data given in Tech. Paper 445 and Circular 6337 of the U. S. Bureau of Mines, have been selected for presentation in Table 1, although the differences from values given by other authorities are small. These molal specific heats are expressed in B.t.u. per lb.-mol per deg. F., and the temperatures in the equations are deg. F.

Instantaneous molal specific heat at constant volume $mc_v = mc_p - 1.985$. The instantaneous specific heats per pound can be found by dividing each of the molal specific heats by the molecular weight of the gas.

All the instantaneous molal specific heat equations take the general form of

$$mc_p = a + bt + dt^2 + et^3.$$

The Quantity of Heat Added to a mol of gas in raising its temperature from t_1 to t_2 at constant pressure

$$= (t_2 - t_1)[a + {}^1/_2\,b\,(t_2 + t_1) + {}^1/_3\,d\,(t_2^2 + t_2 t_1 + t_1^2) + {}^1/_4\,e\,(t_2^3 + t_2^2 t_1 + t_2 t_1^2 + t_1^3)]$$

Mean molal specific heat between t_2 and t_1 is this expression divided by $(t_2 - t_1)$, that is $a + {}^1/_2\,b\,(t_2 + t_1) + {}^1/_3\,d\,(t_2^2 + t_2 t_1 + t_1^2) + {}^1/_4\,e\,(t_2^3 + t_2^2 t_1 + t_2 t_1^2 + t_1^3)$.

The Mean Specific Heat per Pound is found by dividing the mean molal specific heat by the molecular weight m of the gas.

The instantaneous specific heats per pound derived from the molal specific heats in Table 1 and the molecular weights in Table 3, are given in Table 2.

When many computations must be made involving the enthalpy or heat contents of gases at various temperatures, the work may be lessened by means of curves. Enthalpy may be computed at certain temperatures and curves drawn on a sufficiently large scale

Table 1.—Instantaneous Molal Specific Heats at Constant Pressure, mc_p

CO_2	$= 8.999 + 0.002709\,t - (10^{-7} \times 2.56\,t^2)$
H_2O	$= 8.319 + 0.0003364\,t + (10^{-7} \times 6.879\,t^2) - (10^{-10} \times 1.054\,t^3)$
N_2, O_2, CO and air	$= 6.923 + 0.0003734\,t + (10^{-8} \times 4.01\,t^2)$
H_2	$= 6.935 + 0.000217\,t + (10^{-8} \times 6.79\,t^2)$
CH_4	$= 8.35 + 0.00533\,t$ (up to 261° F.) *
$C_nH_{(2n+2)}$	$= 4.19 + 4.29\,n + (0.00666 + 0.00333\,n)\,t$
n	= number of carbon atoms in the molecule.

* For CH_4 at temperatures above 261° F. the formula of Goodenough and Felbeck, *Bull.* 139, Engg. Exp. Sta., Univ. of Illinois, may be used, *viz.*, $CH_4 = 8.312 + 0.01056\,t$ (above 261° F.).

† CH_4	$= 0.5185 + 0.0006587\,t$ (above 261° F.)
C_2H_4	$= 0.4556 + 0.0004752\,t$

* Temperatures t are in deg. F. † Formula by Goodenough and Felbeck.

per mol (or B.t.u. per lb. or per cu. ft. under given conditions if needed) as ordinates and temperatures in deg. F. as abscissæ. The heat added to or subtracted from a unit quantity of a gas between any two temperatures can be found from the curve as the difference in enthalpy at the two temperatures. The mean specific heat of the unit quantity between these two temperatures also can be computed by dividing this difference in enthalpy by the temperature change.

THE INTERNAL ENERGY of a perfect gas has been shown by Joule to depend on temperature only, and to be independent of volume.

The Change in Internal or Intrinsic Energy of 1 lb. of gas

$$778\ (U_1 - U_0) = K_v\ (T_1 - T_0) = R\ (T_1 - T_0)/(\gamma - 1).$$

The total internal energy of w lb. of gas, wU_1, at pressure P_1 in lb. per sq. ft. absolute and volume v_1 in cu. ft., with $\gamma = c_p/c_v$, would be $P_1 v_1/(\gamma - 1)$ measured above absolute zero F., if the substance should follow perfect gas laws down to absolute zero and its specific heats should be constant. When air is expanded or compressed isothermally, Pv = constant, and the internal energy remains constant, the work done in expansion = the heat added, and the work done in compression = the heat rejected.

Work Done in Reversible Adiabatic Expansion, no transmission of heat, from

$$P_1 v_1 \text{ to } \quad : P_1 v_1 \{1 - (v_1/v_2)^{\gamma - 1}\} \div (\gamma - 1) = (P_1 v_1 - P_2 v_2) \div (\gamma - 1)$$
$$= P_1 v_1 \{1 - (P_2/P_1)^{\gamma - 1/\gamma}\} \div (\gamma - 1).$$

Work of Reversible Adiabatic Compression from $P_1 v_1$ to $P_2 v_2$ (P_2 here being the higher pressure) $= P_1 v_1 \{(v_1/v_2)^{\gamma - 1} - 1\} \div (\gamma - 1) = (P_2 v_2 - P_1 v_1) \div (\gamma - 1) = P_1 v_1 \{(P_2/P_1)^{\gamma - 1/\gamma} - 1\} \div (\gamma - 1)$.

Loss of Internal Energy in ft.-lb. per lb. of substance in any expansion or gain in compression $= K_v\ (T_1 - T_2)$, T_1 being the higher temperature.

Work of Isothermal Expansion, in ft.-lb. per lb. from P_1 to P_2, temperature remaining constant = heat expended $= P_1 v_1 \log_e (v_2/v_1) = P_1 v_1 \log_e r = RT \log_e r$, where $r = v_2/v_1$.

Work of Isothermal Compression in ft.-lb. per lb. of substance from P_1 to P_2, $= P_1 v_1 \log_e r = RT \log_e r$ = heat discharged, where $r = P_2/P_1$.

Relation between Pressure, Volume and Temperature for reversible adiabatic changes.

$$P_2 = P_1$$

$$P_1 v_1^{\gamma} = P_2 v_2^{\gamma};\ c_p/c_v = \gamma.$$

For air, $\gamma = 1.40$; $1/\gamma = 0.7143$; $1/(\gamma - 1) = 2.5$; $\gamma/(\gamma - 1) = 3.5$; $(\gamma - 1)/\gamma = 0.2857$

CHARACTERISTIC EQUATION FOR REAL GASES.—Although gases have varying specific heats, in general as can be shown by Table 3, the difference $m(c_p - c_v)$ remains a constant. mR also is substantially constant for real gases and is called the "Universal Gas Constant." Hence one may assume that $Pv = RT$ may be used for 1 lb. of actual gas.

DALTON'S LAW OF GASEOUS PRESSURES.—Every portion of a mass of gas enclosed in a vessel contributes to the pressure against the sides of the vessel the same amount that it would have exerted by itself had no other gas been present.

That is, the total pressure in the vessel is the sum of the partial pressures of each of the constituent gases.

Table 3.—Gas Constants

For a temperature of 32° F. and an absolute pressure of 14.696 lb. per sq. in.

Name of Gas and Formula	Exact Molecular Weight	c_p B.t.u. per lb.	c_v B.t.u. per lb.	$\gamma = \frac{c_p}{c_v}$	$R = 778.6 \times (c_p - c_v)$	v_s = Specific Volume, cu. ft. per lb.	Density, lb. per cu. ft. $= \frac{14.696 \times 144}{491.6} = 4.3048/R$
Air	(28.95)	0.2396	0.1710	1.40	53.39	12.40	0.08063
Carbon monoxide, CO	28.000	0.2477	0.1768	1.401	55.19	12.82	0.07799
Hydrogen, H_2	2.015	3.445	2.460	1.40	767.0	178.18	0.00561
Nitrogen, N_2	28.016	0.2475	0.1767	1.401	55.16	12.81	0.0780

MIXTURES OF VAPORS AND GASES.—The pressure exerted against the interior of a vessel by a given quantity of a perfect gas enclosed in it is the sum of the pressures which any number of parts into which such quantity might be divided would exert separately, if each were enclosed in a vessel of the same bulk alone, at the same temperature. Although this law is not exactly true for any actual gas, it is very nearly true for many.

EXAMPLE.—0.12344 lb. of CO_2 at 32° F., enclosed in a vessel of 1 cu. ft. capacity, exerts a pressure of 1 atmosphere; consequently, if 0.080728 lb. of air, the weight of 1 cu. ft. at 32° F., and 14.7 lb. per sq. in. absolute, and 0.12344 lb. of CO_2 be mixed, and enclosed at the temperature of 32° F., in a vessel of 1 cu. ft. capacity, the mixture will exert a pressure of 2 atmospheres.

As a second example, let 0.080728 lb. of air, at 212° F., be enclosed in a vessel of 1 cu. ft. capacity; it then will exert a pressure of $(212 + 459.2)/(32 + 459.2) = 1.366$ atmospheres. Let 0.03728 lb. of steam, at 212° F., be enclosed in a vessel of 1 cu. ft. capacity; it will exert a pressure of one atmosphere. Consequently, if 0.080728 lb. of air and 0.03728 lb. of steam be mixed and enclosed together, at 212° F., in a vessel of 1 cu. ft. capacity, the mixture will exert a pressure of 2.366 atmospheres.

If 0.0591 lb. of air (= 1 cu. ft. at 212° and atmospheric pressure) is contained in a vessel of 1 cu. ft. capacity, and water at 212° is introduced, heat at 212° being furnished by a steam jacket, the pressure will rise to two atmospheres.

If air is present in a condenser along with water vapor, the pressure is that due to the temperature of the vapor plus that due to the quantity of air present at its partial pressure.

GENERAL EQUATIONS.—Let w_m be the weight of a mixture of gases of volume v_m at absolute temperature T_m, whose individual weights are $w_1, w_2, w_3 \ldots . w_n$, and whose partial pressure are $P_1, P_2, P_3, \ldots . P_n$ respectively,

then $$w_1 \cdot \quad \cdot w_3 \cdot \quad + w_n = \Sigma w$$

$$v_m = v_1 = v_2 = v_3 = \ldots . v_n. \quad T_m = \text{constant}$$

$$P_m = P_1 + P_2 + P_3 + \ldots . P_n = \Sigma P$$

But $$P_1 = w_1 R_1 T_m/v_m, \text{ and } P_2 = w_2 R_2 T_m/v_m. \therefore P_m = \{\Sigma(wR) \cdot T_m\}/v_m$$

But for a mixture, $P_m = (w_m R_m T_m)/v_m. \quad \therefore R_m = (\Sigma wR)/w_m.$

Also the specific heat at constant pressure of a mixture

$$c_{pm} = (\Sigma wc_p)/w_m, \text{ and } c_{vm} = (\Sigma wc_v)/w_m.$$

If a specific heat equation of the form $mc_p = a + bT + dT^2 + eT^3$ is to be written for a mixture of gases, then $a_m = (\Sigma wa)/w_m$; $b_m = (\Sigma wb)/w_m$; $d_m = (\Sigma wd)/w_m$; $e_m = (\Sigma we)/w_m$, where m = molecular weight, c_p = specific heat per lb. at constant pressure, and a_m, b_m, d_m, and e_m are the coefficients for the mixture. The use of such values may simplify heat computations in a mixture of constant composition, as air or natural gas.

POLYTROPIC CHANGES are those which may be represented on a pressure-volume diagram by a curve following the law Pv^n = constant where n is also a constant. These occur in air compressors, air engines, gas and oil engines. When $P_1 v_1{}^n = P_2$ then

$$\text{or} \quad \left(\frac{P_1}{P_2}\right) = \left(\frac{T_1}{T_2}\right)^{n/(n-1)}$$

The work done, $W \quad \dfrac{P_1 v_1 - P_2 v_2}{n - 1}$ ft.-lb., or $Q = w\left(\dfrac{\gamma - n}{n - 1}\right) c_v (\quad T_2)$

where $\gamma = c_p/c_v$ for the gas or mixture of gases.

To Find n from a Given Curve, which follows the law Pv^n = constant, plot successive values of P and v on logarithmic cross-section paper. All points should be on a straight line if n is a constant. By choosing two points on this line $P_1 v_1$ and $P_2 v_2$, then $n = (\log P_1 - \log P_2)/(\log v_2 - \log v_1)$.

FLOW OF FLUIDS.—According to the equation of continuity, the sum of the enthalpy and kinetic energy of a fluid remains constant at all stages of its flow, provided there is no loss or gain of heat to the outside and no work is done. Hence

$$778.6\,h_1 + V_1{}^2/2g = 778.6\,h_2 + V_2{}^2/2g = 778.6\,h_n + V_n{}^2,$$

where $h_1, h_2, \ldots . h_n$ = enthalpy per lb., B.t.u., and V_1, V_2, V_n = velocities, ft. per sec., at the various state points $1, 2, \ldots . n$.

Also at any point the equation of the continuity of mass will represent conditions thus,

$$w = A_1 V_1/v_{1s} = A_2 V_2/v_{2s} = A_n V_n/v_{ns},$$

where w = weight of steam, lb. per sec., $A_1, A_2, \ldots . A_n$ = area of section, sq. ft., and v_{1s}, $v_{2s} \ldots . v_{ns}$ = specific volume of fluid, cu. ft. per lb.

THE DISCHARGE OF A FLUID THROUGH AN ORIFICE from a vessel at pressure P_1 into a region where pressure P_2 is lower than P_1 but not below the critical pressure is given by the equation $w = A\sqrt{2g\dfrac{P_1}{v_1} \cdot \dfrac{\gamma}{\gamma - 1}\left[\left(\dfrac{P_2}{P_1}\right)^{2/\gamma} - \left(\dfrac{P_2}{P_1}\right)^{(\gamma+1)/\gamma}\right]}$.

where w = weight of fluid, lb. per sec.; A = area of orifice, sq. ft.; P_1 and P_2 = absolute

pressures, lb. per sq. ft.; $g = 32.16$; v_1 = specific volume at pressure P_1, cu. ft. per lb.; γ = exponent in equation for the expansion of the gas, *i.e.*, $P_1 v_1^{\gamma} = P_2 v_2^{\gamma}$.

Critical Pressure.—The flow is a maximum when the absolute pressure P_t at the throat of the orifice is $P_t = P_1 \left(\frac{2}{\gamma + 1}\right)^{\gamma/(\gamma - 1)}$. This pressure is called *Critical Pressure.* The discharge remains constant at the critical pressure value for all pressures P_2 below the critical pressure. For air, $\gamma = 1.4$ and $P_t = 0.528\, P_1$. For superheated steam $\gamma = 1.3$ and $P_t = 0.5457\, P_1$.

Also, since $P_1 v_1^{\gamma} = P_t v_t^{\gamma}$, where v_t = specific volume at the critical pressure P_t, and $P_t = P_1 \left(\frac{2}{\gamma + 1}\right)^{\gamma/(\gamma - 1)}$, $P_1 v_1 = \frac{\gamma + 1}{2} P_t v_t$; the velocity of discharge, V_t at the throat, in ft. per sec., at the critical pressure is

$$V_t :$$

which latter equation is the velocity of sound in the fluid, and often is called the *acoustic velocity.*

FLOW OF GASES.—By the principle of the conservation of energy, it may be shown that the velocity with which a gas under pressure will escape into a vacuum is inversely proportional to the square root of its density; that is, oxygen, which is sixteen times as heavy as hydrogen, would, under exactly the same circumstances, escape through an opening only one-fourth as fast as the latter gas.

3. IDEAL CYCLES

THE CARNOT CYCLE.—Let one pound of gas of an absolute pressure P_1, volume v_1 and absolute temperature T_1 be enclosed in an ideal cylinder, having non-conducting walls but with the bottom a perfect conductor, and having a moving non-conducting frictionless piston. Let the pressure and volume of the gas be represented by the point 1 on the *Pv* or pressure-volume diagram, Fig. 1, and let it pass through four operations, as follows:

1. Apply heat at temperature T_1 to the bottom of the cylinder and let the gas expand, doing work against the piston, at the constant temperature T_1, or isothermally, to $P_2 v_2$ or 2. For isothermal $P_1 v_1 = P_2 v_2$. All pressures are absolute.

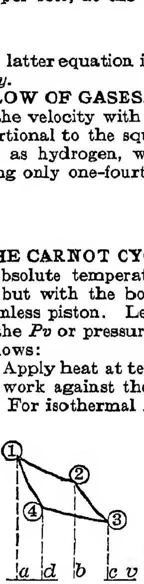

Fig. 1

2. Remove the source of heat, put a non-conducting cover on the bottom, and let the gas expand adiabatically isentropically without eddies or losses or without transmission of heat, to $P_3 v_3$, or 3, while its temperature is being reduced to T_2.

3. Apply to the bottom of the cylinder a cold body, or refrigerator, of temperature T_2, and let the gas be compressed by the piston isothermally to the point 4, or $P_4 v_4$, rejecting heat into the cold body. $P_3 v_3 = P_4 v_4$.

4. Remove the cold body, restore the non-conducting bottom, and compress the gas, adiabatically and isentropically without losses or transmission of heat, to 1, or the original $P_1 v_1$, while its temperature is being raised to the original T_1. The point 4 on the isothermal line 3-4 is so chosen that an isentropic line passing through it also will pass through 1, and so that $v_1/v_4 = v_2/v_3$, and let $v_2/v_1 = r = v_3/v_4$.

The area *a*123*c* represents the work done by the gas on the piston, the area *c*341*a* the negative work, or the work done by the piston on the gas, the difference 1234, is the net work.

1*a*. The area *a*12*b* represents the work done during isothermal expansion. It is equal in ft.-lb. to $W_1 = P_1 v_1 \log_e (v_2/v_1)$, $= P_1 v_1 \log_e r = RT_1 \log_e r$, where P_1 = initial absolute pressure, lb. per sq. ft., and v_1 = the initial volume in cu. ft. It also is equal to the quantity of heat supplied to the gas, $Q_1 = ART_1 \log_e (v_2/v_1)$ in B.t.u. $A = 1/778.6$. R is a constant for a given gas or mixture of gases. See Table 3.

2*a*. The area *b*23*c* is the work done during adiabatic expansion

$\gamma \cdot \quad \{1 - \quad {}^{\gamma - 1}\}$ $\gamma = c_p/c$ = ratio of the specific heat at constant pressure to the specific heat at constant volume. The loss in internal energy during this expansion $= 778.6\, c_v (T_1 - T_2)$ in ft.-lb.

3*a*. *c*34*d* is the work of isothermal compression

$$= W_3 = P_4 v_4 \log_e (v_3/v_4) = P_4 v_4 \log_e r = RT_2 \log_e r.$$

This is equivalent to the heat rejected $= Q_2 = ART_2 \log_e$ in B.t.u.

4*a*. *d*41*a* is the work of adiabatic compression

$$= W = \frac{P_1 v_1}{} \left(\quad \right)^{\gamma - 1}$$

which is the same as W_2, and therefore, being negative, cancels it The net work 1234 $W_1 - W_3$. The gain in internal energy during the compression $d41a = 778.6\, c_v\, (T_1 - T$ in ft.-lb.

$$\text{Efficiency} = \frac{W_1}{Q_1} = \frac{R\,(T_1 - \quad) \log_e r}{} = \frac{T_1 - T_2}{} = 1 - \frac{T_2}{}$$

The Carnot Cycle in the Temperature-entropy Diagram.—Let the pound of gas of temperature T_1 and entropy s be subjected to the four operations described above. 1. T_1 being constant, heat (area *a*12*c*, Fig. 2) is added; entropy increases from 1 to 2, isothermal expansion. 2. No heat is transferred, but the temperature is reduced from T_1 to T_2, entropy constant, isentropic adiabatic expansion from 2 to 3. 3. Heat is rejected at the constant temperature T_2, the area *c*34*a* being subtracted; entropy decreases from 3 to 4, isothermal compression. 4. Entropy constant, temperature increases from 4 to 1, or from T_2 to T_1, no heat transferred, isentropic adiabatic compression. The area *a*12*c* represents the total amount of heat added during the cycle, the area *c*34*a* the amount of heat rejected, the difference, or the area 1234, is the heat converted into work. The ratio of this area to the whole area *a*12*c* is the efficiency. It is the same as the ratio $(T_1 - T_2)/T_1$. It appears from this diagram that the efficiency may be increased by increasing T_1 or by decreasing T_2; also since T_2 cannot be lowered by any self-acting engine below the temperature of the surrounding atmosphere, say $460° + 62°$ F. $= 522°$ F., it is not possible, even in a perfect engine, to obtain an efficiency of 50% unless the temperature of the source of heat is above 1000° F. It is shown also by this diagram that the Carnot cycle gives the highest possible efficiency of a heat engine working between any given temperatures T_1 and T_2, and that the admission and rejection of heat, each at a constant temperature, gives a higher efficiency than the admission or rejection at any variable temperatures within the range $T_1 - T_2$.

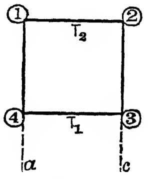

Fig. 2

THE REVERSED CARNOT CYCLE—REFRIGERATION.—Let a pound of cool gas whose temperature and entropy are represented by the *state-point* 4 on the diagram: 1. Receive heat at a constant temperature T_2 (the temperature of a refrigerating room) until its entropy is 3. 2. Let it be compressed isentropically (no losses as 3–2) to a high temperature T_1. 3. Let it reject heat into the atmosphere at this temperature, T_1 (isothermal compression). 4. Let it expand isentropically again with neither friction, eddy, nor other losses, 1–4, doing work by pushing a piston. It then will cool to a temperature which may be far below that of the atmosphere and be used to absorb heat from the refrigerating room. (See Refrigeration, p. 10–11.)

4. VAPORS

A VAPOR is a substance in a condition intermediate between the liquid and gaseous states, and such that it fills the entire container, thereby exerting a pressure as does a gas, but does not follow the laws of ideal gases even approximately.

A liquid when heated at constant pressure reaches a temperature, depending on the pressure, at which it commences to change its physical state to a vapor at that constant temperature. At temperatures below the boiling point the water is *subcooled*. When the liquid reaches the boiling point under these conditions, its energy is called the *saturated heat of the liquid.*

The heat added to complete evaporation at constant pressure and temperature at the boiling point is the *latent heat of vaporization.* When the last particle has been evaporated but the temperature has not risen above the boiling point, the vapor is *dry and saturated.* Any conditions in which droplets of liquid in the form of fog are suspended in the vapor and are not completely evaporated produces a *wet* mixture. The mixture has the same temperature as dry saturated vapor at the same pressure. The ratio of completely evaporated liquid to total substance present in such a wet mixture is known as the *percent quality.* Thus, if 2% of moisture is present as droplets, the quality is 98%. If the dry

and saturated vapor is still further heated, its temperature rises and it becomes *superheated.* In this condition it approximately follows the laws of perfect gases. The *degree of superheat* is the difference between the actual temperature of the superheated vapor and the boiling temperature at the same pressure.

In every liquid there is a certain pressure at which the saturated liquid changes into vapor, with no change in volume and with the addition of no latent heat. This is the *critical state.*

THE ENTHALPY (OR TOTAL HEAT) PER POUND OF LIQUIDS AND VAPORS is expressed by the general equation $h = U + A\,P\,v$, as in perfect gases, where h = enthalpy per lb., B.t.u.; U = internal energy, B.t.u. per lb.; $A = 1/778.6$; P = absolute pressure, lb. per sq. ft.; v = specific volume, cu. ft. per lb.

If v_f = volume of 1 lb. of saturated liquid at a given pressure, and v_g = volume of 1 lb. of dry and saturated vapor at the same pressure, the increase in volume during vaporization is $(v_g - v_f) = v_{fg}$. The volume of the mixture at any quality x is therefore $v_x = v_f + x(v_g - v_f) = v_f + xv_{fg}$.

If h_f = enthalpy or total heat above 32° F. of 1 lb. of saturated liquid at a given pressure in B.t.u., h_{fg} = heat of vaporization of 1 lb. at the same pressure, in B.t.u., and x = quality of the mixture, the *enthalpy or total heat of* 1 *lb. of the mixture* in B.t.u. = $h_x = h_f + xh_{fg}$

SATURATION POINT OF VAPORS.—A vapor that is not near the saturation point behaves like a gas under changes of temperature and pressure. But if it is sufficiently compressed or cooled, it reaches a point where it begins to condense. It then no longer obeys the same laws as a gas, since its pressure cannot be increased by diminishing the size of the vessel containing it, but remains constant, except when the temperature is changed. The only gas that can prevent a liquid evaporating seems to be its own vapor.

The properties of the various vapors such as steam, ammonia, carbon dioxide, etc., and the discussion of humidity are given in other sections of this book.

ABSORPTION OF GASES BY LIQUIDS.—Many gases are absorbed readily by water. Other liquids also possess this power in a greater or less degree. Water will, for example, absorb its own volume of CO_2, 800 times its volume of NH_3, 2 1/3 times its volume of chlorine, and only about 1/20 of its volume of oxygen.

The weight of gas that is absorbed by a given volume of liquid is proportional to the pressure. But as the volume of a mass of gas is less as the pressure is greater, the volume which a given amount of liquid can absorb at a certain temperature will be constant, whatever the pressure. Water, for example, can absorb its own volume of CO_2 at atmospheric pressure; it also will dissolve its own volume if the pressure is twice as great, but in that case the gas will be twice as dense, and consequently twice the weight of gas is dissolved. This principle is the basis of deaeration of condensate in surface condensers.

Table 4 gives the critical temperature and critical pressure of some gases that have been liquefied. The critical temperature is that at which the properties of a liquid and its vapor are indistinguishable, and above which the vapor cannot be liquefied by compression. The critical pressure is the pressure of the vapor at the critical temperature.

COMBUSTION AND FUELS

COMBUSTION

By Robert Thurston Kent

1. HEAT OF COMBUSTION

THE COMBUSTIBLE CONSTITUENTS of fuel are carbon, hydrogen, sulphur and hydrocarbons. Other constituents are oxygen, nitrogen, moisture and ash. In burning, the combustibles combine with oxygen in the air and in the fuel to form carbon dioxide, carbon monoxide, sulphur dioxide and water. The ash includes all non-combustible matter.

With sufficient air supplied to effect complete combustion carbon burns to CO_2. With insufficient air, it burns to CO. If additional air is supplied, the CO will burn to CO_2.

The hydrocarbons burn to CO_2 and steam. If the temperature is too low for ignition they will pass off unburned. If the air supply is deficient, they will break down to hydrogen and carbon, the latter burning to CO_2 if later brought into contact with sufficient hot air; otherwise it will appear as smoke or soot. The total heat of combustion of any hydrocarbon compound, except CH_4, is approximately the sum of the heats of combustion of the constituents burned separately.

The hydrogen burns to water. Hydrogen and oxygen combined in the fuel as water, or existing in other constituents in the proportions of water are neglected in determining the heating value of the fuel. If the water, actually or virtually present in the fuel, is in sufficient quantity to make its latent heat of evaporation an appreciable quantity, that latent heat is deducted from the heating value of the fuel. Only the excess of hydrogen above that required to form water when combined with the oxygen in the fuel is considered in determining heating value.

Nitrogen in fuel is inert, and is not burned. Nitrogen in the air enters the furnace at atmospheric temperature and leaves it at the temperature of the chimney gases. It is the chief source of heat loss in furnace operation.

Sulphur in fuel is objectionable, as it causes clinker to form. It may exist as iron sulphide or sulphate of lime. The latter form has no heating value.

HEAT OF COMBUSTION. DULONG'S FORMULA.—The heat of combustion of any substance may be determined by burning it in oxygen in a calorimeter (see below), or approximately by Dulong's formula. Let C, H and O equal, respectively, the percentages by weight of carbon, hydrogen and oxygen in 1 lb. of fuel. Then

$$\text{B.t.u. per lb.} = 14{,}600\ C + 62{,}000\ (H - {}^1/_8\,O) + 4000\,S.$$

If the fuel contains CO, the formula is modified to

B.t.u. per lb. $= 14{,}600\,C + 62{,}000\ (H - {}^1/_8\ O) + 4000\,S + 10{,}150\,C_1$, where C_1 = proportionate part of carbon burned to CO. The formula does not hold for methane, CH_4, but appears to hold for ethylene, C_2H_4, and benzole, C_6H_6. Dulong's formula has a probable error not exceeding 2%. Its accuracy has been proved both by Mahler and by Lord and Hass. A deviation in calorimeter tests of more than 2% in the heating value as calculated by the formula (lignites and cannel coals excepted) probably is due to an error in calculation or in the calorimeter test, rather than to the formula.

In calculations of heating value, heat of combustion of hydrogen usually is taken as 62,000 B.t.u. per lb.; of carbon burned to CO_2 as 14,600 B.t.u. per lb. If carbon is burned to CO its heating value is taken as 10,150 B.t.u. per lb. Table 1 gives the heat of combustion of the various constituents of fuels when burned in oxygen.

The total heat of combustion of hydrogen is not available, unless the products of combustion are cooled to the initial temperature of the gases. Since hydrogen burns to steam, a portion of the heat evolved is latent in the steam. The difference between the total heat of combustion, termed the *high heating value*, and the latent heat of the steam is the *low heating value* of hydrogen. The low heating value should not be used in computations concerning fuels containing hydrogen, unless a complete statement is given of all the conditions surrounding combustion. Commercial fuels are burned in air instead of in oxygen, usually with an excess of air. The gases of combustion are discharged at

high temperatures and the steam formed by combustion is superheated to the temperature of the escaping gases. Both cause loss of available heat.

EXAMPLE.—Determine the available heating value of 1 lb. of hydrogen, burned in twice the quantity of air at 62° F. required for combustion, gases of combustion escaping at 562° F.

Solution.—

High heating value of H, determined by calorimeter		62,000 B.t.u.
9 lb. of water heated from 62° to 212° F.	1349.6 B.t.u.	
Latent heat of 9 lb. of water at 212°, 9 × 970.2	8731.8	
Heat required to superheat 9 lb. of steam to 562° F. (specific heat = 0.48), 9 × (562 − 212) × 0.48	1512.0	
Heat required to heat 26.56 lb. of nitrogen to 562° F. (specific heat = 0.2438), 26.56 × (562 − 62) × 0.2438	3237.6	
Heat required to heat 34.56 lb. excess air to 562° F. (specific heat = 0.2375), 34.56 × (562 − 62) × 0.2375	4104.0	
Total heat losses		
Net available heating value		43,065 B.t.u.

CALORIMETERS used to determine heats of combustion are of the bomb type, first devised by M. Pierre Mahler. Some type of adiabatic calorimeter generally is used for precise work. In the bomb calorimeter a weighed sample of the fuel is burned in the bomb, in the presence of oxygen, at a pressure of about 350 lb. per sq. in. The bomb is immersed in a weighed bath of water, and the rise in temperature of the water is noted. From the known weights of water and fuel, the known constants and the temperature rise of the calorimeter, the heat of combustion of the fuel is determined.

The Parr Adiabatic Calorimeter is of the oxygen bomb type, water jacketed. A 1-gram sample is burned in a closed bomb containing oxygen under a pressure of 500 lb. per sq. in. In Fig. 1, the bomb B is submerged in 2000 millileters of distilled water in an oval bucket A, completely surrounded by a water jacket C_1, C_2. Impellers F maintain circulation through the jacket. Sensitive thermometers, D_1, D_2, enter both bucket and jacket. The sample in the bomb is ignited electrically, and as the temperature in the bucket rises, the temperature of the jacket is kept in equilibrium with it by injecting hot water through jet E. This prevents radiation and conduction losses from the bucket A, and the rise in the thermometer D_1 indicates the true heat input due to combustion in the bomb B plus the heat due to fuse wire and formation of acids. Excess water overflows at G. The temperature rise multiplied by the water equivalent of the instrument, gives the uncorrected thermal value of the sample. By deducting the heat due to fuse wire and acids, the true thermal value of the sample is obtained. If Fahrenheit thermometers are used, the result will be in B.t.u. per lb., and if Centigrade thermometers are used the result will be in calories per gram. It is to be noted that in this calorimeter, two major provisions are made for the elimination of errors: 1. The thermally-controlled water jacket bars radiation at its source. 2. The bomb is made of a metal or alloy highly resistive to attack by hot nitric and sulphuric acids; thus in the absence of corrosion, true corrections for the formation of acids are obtained. The results, therefore, are devoid of errors due either to radiation or to corrosion. The water equivalent, or total specific heat, for the instrument is determined by the combustion of a uniform material of known heat value, such as benzoic acid, under conditions identical to those present during the test of an unknown material. The factor thus may be applied directly.

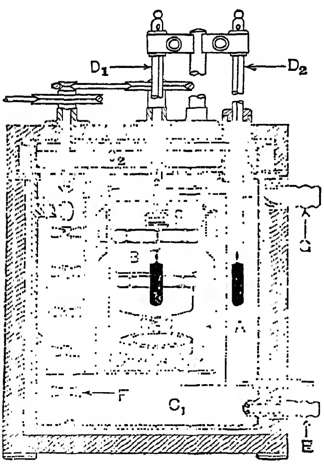

FIG. 1. Parr Adiabatic Calorimeter

HEATING VALUE OF COMPOUND OR MIXED FUELS is the sum of the heating value of their constituents. It is calculated by Dulong's formula, above.

HEAT ABSORBED BY DECOMPOSITION.—The same amount of heat is required to break down a compound as is evolved in its formation. Thus, if 1 lb. of carbon is burned to CO_2 and the CO_2 thus formed is reduced to CO by exposure to glowing carbon, the re-

* Measured as a gas at 62° F. and 14.7 lb. per sq. in. pressure.

sult is the same as if the 2 lb. of carbon had been burned directly to CO. The reactions are

$$2C + 2O_2 = 2CO_2, \text{ generating } 2 \times 14{,}600 = 29{,}200 \text{ B.t.u.}$$

$$C + CO_2 = 2CO, \text{ generating } 2 \times 4450 = 8900 \text{ B.t.u.}$$

The difference, 20,300 B.t.u. is the heat required to liberate 2 lb. of carbon from the CO, or 10,150 B.t.u. per lb. of carbon.

Similarly, if 9 lb. of steam be injected into a bed of glowing coal, it will decompose into 1 lb. H and 8 lb. O, abstracting 62,000 B.t.u. from the bed of coal. If additional air is supplied the hydrogen again will burn to steam, evolving 62,000 B.t.u., and the 8 lb. of oxygen will combine with 6 lb. of carbon to form 14 lb. CO, generating 6 × 4450 = 26,700 B.t.u., or it will combine with 3 lb. of carbon to form 11 lb. CO_2, generating 3 × 14,600 = 43,800 B.t.u.

TEMPERATURE OF THE FIRE.—Let T and t = respectively, temperature of the fire and of the air supplied for combustion, deg. F.; h = total heating value of the fuel; W and S = respectively, weight and specific heats of gases of combustion. Then $T = \{h/(W \times S)\} + t$. Theoretically, rapidity of combustion does not affect temperature. Practically, radiation reduces the temperature of the fuel bed and the gases immediately above it, and considerable heat may be lost if combustion is slow. Usually, at ordinary rates of combustion, in firebrick boiler furnaces, radiation loss is not over 1%, and the temperature of the fire will be almost as high at a combustion rate of 10 lb. per sq. ft. of grate per hr. as at a rate of 20 or 40 lb.

Theoretical temperatures are attained only if the gases combine instantaneously and simultaneously throughout their mass. Evolution of heat is retarded by dissociation and the cooling effect of the sides of the furnace. Also, the specific heat of gases increases at very high temperatures.

To attain high temperature, air must be delivered to the incandescent fuel at a uniform rate, and combustion of carbon and hydrogen must be complete, carbon burning to CO_2 when 11.52 lb. of air or more is supplied per 1 lb. of carbon. If less air is supplied, all the oxygen is used to form CO or CO_2. Also, with insufficient air some oxygen passes through the fire without combining with the carbon. An excess of air also will decrease the temperature. Radiation from the incandescent fuel bed to the surrounding furnace or boiler walls must be prevented to obtain maximum temperatures. The nearest approach to maximum temperature conditions is with gaseous or dust fuels, with an intimate and regular admixture of air in a thick-walled firebrick combustion chamber.

TEMPERATURE OF THE FIRE, FUEL CONTAINING HYDROGEN AND WATER (William Kent, Steam Boiler Economy, 2d. edition, p. 29).—The following assumptions are made: Hydrogen and water exist in the combustion chamber as superheated steam at

the temperature of the fire; specific heat of the gases of combustion is constant at 0.237. The last assumption is probably in error as the specific heat of gases increases with temperature, but the effect is negligible when relative figures only are desired. Let C, H, O and W = respectively, the percentage, by weight, of carbon, hydrogen, oxygen, and water in the fuel; T = temperature of the fire, deg. F.; t = temperature of the atmosphere, deg. F.; f = pounds of dry gas per pound of fuel. Then, approximately,

$$T = \frac{616\,C + 2220\,H - 327\,O - 44\,W}{f + 0.02\,W + 0.18\,H} + t$$

Example.—Required the maximum temperature from combustion of wood of composition C, 38; H, 5; O, 32; ash, 1; moisture, 24. Dry gas per lb. of wood = 15 lb.; atmospheric temperature, 62° F.

$$T = \frac{(616 \times 38) + (2220 \times 5) - (327 \times 32) - (44 \times 24)}{15 + (0.02 \times 24) + (0.18 \times 5)} + 62 = 1503° \text{ F.}$$

Temperature Due to Burning Carbon in Dry Air.—One pound of carbon burned to CO_2 in dry air generates 14,600 B.t.u., evolving 8.85 lb. nitrogen, of specific heat 0.2438, and 3.667 lb. of CO_2, of specific heat 0.217. The mean specific heat is 0.2359. Temperature of fire, with atmospheric temperature at 62° F., then is

$$T = \{14{,}600/(8.85 + 3.67) \times 0.2359\} + 62 = 5005° \text{ F.}$$

This temperature cannot be obtained in practice, due to the excess air necessary for complete combustion. Table 2 gives the temperature of the fire with a deficient air supply, and Table 3 gives temperatures with excess air.

2. AIR REQUIRED FOR COMBUSTION

AIR REQUIRED FOR COMBUSTION.—The minimum amount of air required for combustion is determined from the combustion equation, *i.e.*, the chemical equation expressing the reaction of combustion as given in Table 1. Dividing the total molecular weight of the oxygen required for combustion by the total molecular weight of the combustible will give the weight of oxygen required per pound of combustible. Thus in the equation $2\,C + 2\,O_2 = 2\,CO_2$, the total molecular weights of the combustible and oxygen required for combustion are 24 and 64, respectively. The oxygen required for combustion

Table 2.—Temperature Due to Burning Carbon with Deficient Air Supply

Carbon burned partly to CO_2, partly to CO. Specific heat of gases of combustion assumed = 0.24.

	Deficiency below 11.52 lb. of air per lb. of carbon, percent					
	0	10	20	30	40	50
Lb. of air per lb. of carbon	11.52	10.37	9.22	8.06	6.91	5.76

Total heat generated, B.t.u.	14,600	12,570	10,540	8,510	6,480	4,450
Loss due to CO, B.t.u.	0	2,030	4,060	6,090	8,120	10,150
Elevation of temp. of fire above atmosphere, deg. F.	4,859	4,606	4,297	3,914	3,413	2,743
Gas analysis by volume, percent:						
CO_2	20.86	18.12	14.87	10.94	6.10	0
CO	0	4.53	9.91	16.41	24.42	34.51
N	79.14	77.35	75.22	72.65	69.48	65.49

Table 3.—Temperature Due to Burning Carbon with Excess Air

All carbon burned to CO_2. Specific heat of gases of combustion assumed = 0.24.

	Excess air above 11.52 lb. per lb. of carbon, percent					
	25	50	75	100	150	200
Lb. of air per lb. of carbon	14.40	17.28	20.16	23.04	28.80	34.56
Total gas per lb. of carbon, lb.	15.40	18.28	21.16	24.04	29.80	35.56
Elevation of temp. of fire above atmosphere, deg. F.	3950	3328	2875	2531	2041	1711
Gas analysis by volume, percent:						
CO_2	16.69	13.91	11.92	10.43	8.34	6.95
CO	4.17	6.95	8.94	10.43	12.52	13.91
	79.14	79.14	79.14	79.14	79.14	79.14

then is 64/24 = 2 2/3 lb. per lb. of carbon. Since air is composed of 23.2% oxygen and 76.8% nitrogen, by weight, dividing the weight of the oxygen required by 0.232 will give the minimum weight of air required.

The minimum air required for a compound fuel is calculated by computing the air necessary per lb. of each constituent of the fuel, and then combining the quantities so found in the proportions in which the constituents exist in the fuel. A greater amount of air than the minimum is required in practice. See Temperature of the Fire, above.

EXAMPLE.—Required the minimum quantity of air to burn a coal whose proximate analysis is fixed carbon, 66%; volatile matter, 22%; ash, 12%. Assume all the volatile to be methane, CH_4. *Solution.*—The combustion equations (Table 1), with the respective molecular weights are:

$$\underset{24}{2\,C} + \underset{64}{2\,O_2} = \underset{88}{2\,CO_2}; \qquad \text{oxygen required} = 64/24 = 2\,{}^2/_3 \text{ lb. per lb. C.}$$

$$\underset{16}{CH_4} + \underset{64}{2\,O_2} = \underset{44}{CO_2} + \underset{36}{2\,H_2O}; \qquad \text{oxygen required} = 64/16 = 4 \text{ lb. per lb. } CH_4$$

Since the fuel contains 66% carbon and 22% CH_4, the oxygen required per lb. of fuel will be $(0.66 \times 2.67) + (0.22 \times 4) = 2.64$ lb. of oxygen per lb. of fuel. Air required is $2.64/0.232 = 11.38$ lb. per lb. of fuel.

AIR REQUIRED TO BURN VARIOUS FUELS.—William Kent (Steam Boiler Economy, 2d edition) gives a formula for the air required to burn fuels of known ultimate analysis, based on 50% excess air above that theoretically necessary for complete combustion. Let C, H and O = respectively, the carbon, hydrogen and oxygen in 1 lb. of fuel = percentage ÷ 100. Then

$$\text{Lb. of air per lb. fuel} = 1.5\{11.52\,C + 34.56(H - {}^1/_8\,O)\}$$

The result, divided by the combustible or the carbon per pound of fuel, gives the air required per pound of combustible or per pound of carbon. Table 4 gives the air required on this basis by typical fuels. Table 5 shows the effect of varying quantities of excess air on CO_2 content in the flue gases, flame temperature and heat loss.

Table 4.—Air Required to Burn Various Fuels

Based on 50 percent of excess air

Effect of Preheated Air on Combustion.—P. Nicholls and M. G. Eilers (*Trans.* A.S.M.E. FSP–56–5, May, 1934) describe experiments to determine the effect of varying amounts of air with various coals and high- and low-temperature coke. They show that at each temperature of preheat there is a maximum amount of fuel that can be burned with a given supply of primary air. The maximum varies for each preheat temperature, and an increase in the air supply decreases the amount of fuel that can be burned. They also show that as the size of the coal increased, the rate of combustion with a given amount of air decreased. The authors conclude that preheat gives only limited assistance to combustion, without affecting its value as a means of increasing overall economy. Preheat increases the rate of ignition; based on a normal air temperature of 80° F., preheating to 200° F. increased maximum rate of ignition of Illinois coal 35%, and preheating to 300 increased it 85%. Corresponding figures for Pittsburgh coal were 19% and 43%.

Hosea Webster (*Trans.* A.S.M.E. FSP–51–53, 1929) gives data on the effect of preheated air on boiler efficiency. He cites results of a number of boiler tests from which the following are selected:

	Pulverized Coal	Underfeed Stoker	Chain Grate Stoker	Oil
Efficiency of boiler, percent	82.5	79.9	73.5	69.9
Efficiency of boiler, and air heater, percent	88.2	87.5	82.6	78.4
Gain in efficiency due to air heater, percent	5.7	7.6	9.1	8.5

Highly preheated air may increase stoker maintenance costs. An investigation of a large number of stoker maintenance costs by R. E. Dillon and M. D. Engle (*Trans.* A.S.M.E., FSP–56–17, Dec. 1934) showed that maintenance costs increased sharply with air preheated above 350° F.

FUELS

By Robert Thurston Kent

FUELS IN GENERAL

CLASSIFICATION OF FUELS.—Fuels generally are classified as: 1. Solid, including coal, coke, wood and waste products. 2. Liquid, including petroleum and its derivatives and alcohol. 3. Gaseous, including natural and manufactured gas.

Solid fuels, particularly coal, may be classified in a number of different ways. See paper Constitution and Classification of Coal, H. C. Fieldner, *Trans.* A. S. M. E., FSP–50–51, 1929. They may be classified by *rank*, that is, according to the ratio of fixed carbon to volatile matter in the fuel, peat representing the lowest rank and superanthracite or graphitic coal representing the highest. Table 1 from Fieldner's paper above cited gives the distinguishing chemical and physical characteristics of the various ranks of coal. They also may be classified according to their use, as steam coal, gas coal, etc. Other systems of classification depend on the relations of heating value, proximate analysis and ultimate analysis, as in the Parr system and the Ralston method described below.

Fieldner states that the system of classification based on proximate analysis and calorific values is supplemented by certain physical criteria, especially in differentiating

Table 1.—Chemical and Physical Characteristics of Various Ranks of Coal

Rank, Ash-free	Chemical Characteristics: Approximate Moisture Content*	Chemical Characteristics: Fuel Ratios, FC/VM†	Physical Characteristics
Peat	80–90	....	
Lignite	30–45	....	Brown; clay-like or woody in appearance; slacks on exposure.
Sub-bituminous	12–30	....	Black; disintegrates on exposure, but less rapidly than lignite.
Bituminous	3–15	3 or less	Little or no slacking on exposure to weather.
Semi-bituminous	3–6	3–6	Friable; burns with little smoke.
Semi-anthracite	3–6	4–10	Hard; burns with very little smoke.
Anthracite	2–3	Over 10	Hard; high specific gravity; smokeless.
Superanthracite	2–13	Over 10	Resembles graphite.

* Mine sample. † FC = fixed carbon, percent; VM = volatile matter, percent.

between lignite, sub-bituminous and low-rank bituminous coal. Lignite and sub-bituminous coals disintegrate or slack readily on exposure to weather, the former more rapidly and more completely than the latter. Low rank bituminous coal slacks slowly and incompletely. The slacking is directly proportional to bed moisture in the coal and can be predicted from the moisture content. An accelerated test for slacking characteristics, developed by the U. S. Bureau of Mines, comprises drying for 24 hours of 1 1/2- to 2-in. lumps of coal or lignite of definite weight, at a temperature of 30 to 40 deg. C. The coal then is screened on a 1/4-in. screen and the percentage of undersize determined.

Ralston's Method of Classification is based on taking the sum of the carbon, hydrogen and oxygen of the fuel as 100% and plotting the percentages of these three elements on trilinear coordinates, as in Fig. 1. See O. C. Ralston, Graphic Studies of the Ultimate Analyses of Coal, Tech. Paper No. 93, U. S. Bureau of Mines. A plot of many thousands of coal samples gave a curve that lies in the shaded portion of the lower left hand corner of Fig. 1. For practical use, only the shaded portion of the chart is necessary and it may be reproduced on a much larger scale, as in Fig. 2. Ralston found the fields of the different fuels on the chart to be quite sharply defined as shown in Fig. 2. The analysis of the coal being known, its classification quickly can be determined by locating it on the chart. Thus a fuel, dry and free of ash, whose composition is 74.8 C + 5.2 H + 20 O = 100%, would be located at point 1 in Fig. 2, and would be definitely classified as a lignite.

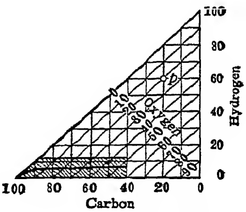

Fig. 1. **Ralston Chart**

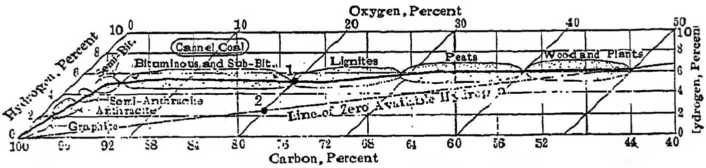
It may be assumed that all the oxygen in the fuel, as determined by analysis, is combined with some of the hydrogen, to form H_2O. This appears combined with carbon in some form of carbohydrate, $C_x\ (H_2O)_y$. From this assumption, a line may be drawn on the chart which is the line of zero available hydrogen. The amount of hydrogen available for combustion then is the difference between the total hydrogen as shown by



. 2. Classification of Coal by Ralston Chart

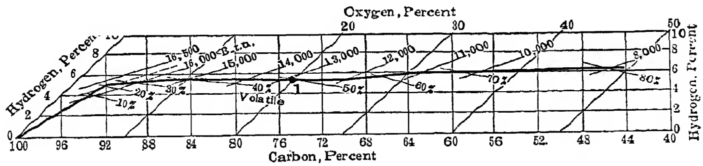


Fig. 3. Ralston Chart with Isocalorific and Isovolatile Lines

analysis and the hydrogen combined with all the oxygen in the form of carbohydrates; for example, the distance on the hydrogen scale between points 1 and 2 in Fig. 2.

If isocalorific and isovolatile lines, *i.e.*, lines showing equal heating values and equal percentages of volatile matter, be superposed on the chart, it may be used to classify a fuel when the percentage of volatile matter and the heating value are known. The percentage of volatile matter is determined by proximate analysis, which should include the sulphur percentage, and in conjunction with the high heating values, reduced to the basis on which the chart is constructed, will locate a point on the isovolatile and isocalorific co-ordinates.

The position of the point determines the classification of the coal and also its approximate composition with respect to carbon, hydrogen and oxygen. See point 1, Fig. 3. Ralston's diagram shows a definite relation to exist between ultimate analysis of a fuel and its calorific value. It permits the application of either ultimate analyses or of volatile matter plus calorific value to the classification of a fuel. It also permits the determination of the volatile matter and calorific value of the fuel from its content of carbon, hydrogen and oxygen.

Parr's System of Fuel Classification is based on the relation of the percentage of volatile matter and the heating value per pound of unit coal. Unit coal is dry coal, ash-free, corrected for contained sulphur, water of hydration and shale. Fig. 4 illustrates the Parr system of classification. See S. W. Parr, The Classification of Coal, *Ind. and Engg. Chem.*, vol. 14, p. 919, 1922.

THE RELATIVE ECONOMY OF VARIOUS FUELS does not depend on the heating value of the fuel itself as much as on the conditions attending its use. Martin Frisch (*Trans.* A.S.M.E., FSP–52–11, 1930) describes boiler tests with the nine fuels shown in Table 2, from which he derives Table 5 showing the relative price that can be paid for different fuels to generate steam at the same total cost with each fuel. The solid fuels were burned in pulverized form. The index of boiler performance used was the sensible heat imparted to the products of combustion per pound passed through the boiler. This index depends on: 1. Heating value of the fuel. 2 The weight of gas and vapor formed by its combustion. 3. The amount of heat made unavailable by incomplete combustion and the evaporation of moisture and formation of water vapor by burning hydrogen. The effect of (2) is small while that of (3) may be large. Excess air influences the magnitude of the index as it affects the total quantity of gas formed per available heat unit. The author presents curves based on this index, which show that the fuels imparting the greatest amount of sensible heat to the flue gases have, in all cases, lower exit temperatures of flue gases and lower draft losses than fuels imparting less sensible heat. See Table 3 compiled from curves in the paper.

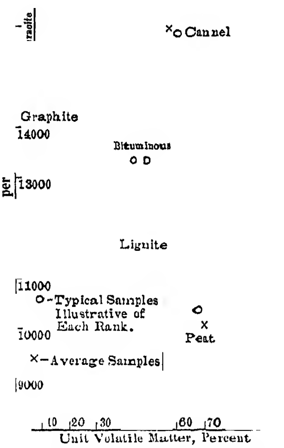

Fig. 4. Parr System of Coal Classification

The capacity developed with a given draft loss increased with the sensible heat per pound of gas passed through the boiler. Flame temperature has a greater effect on capacity than exit temperature. For example, the combustion temperature of natural gas was about 1000° F. higher than that of blast-furnace gas, but the exit temperatures were within 35° F. of each other Preheating the combustion air increased efficiency about 1% at 500% of rating and decreased draft loss over $^3/_4$ in. It also lowered exit temperatures. See also p. 4–08. The difference in efficiency attainable with the different fuels at a given percentage of boiler rating is due also to the completeness of combustion and latent heat losses, which vary with each fuel. Combustion losses with the gaseous fuels and oil are negligible, but the latent heat losses are high, and may exceed 10% with coke-oven and natural gas. With solid fuels burned in pulverized condition the losses due to incomplete combustion and unburned carbon increase with increasing fixed carbon content. Curves in the paper show that the losses due to unburned carbon range about as follows:

B.t.u. liberated per cu. ft. of combustion space	8000	12,000	16,000	20,000	24,000	30,000
Loss due to unburned carbon, percent:						
Anthracite	7.0	7.10	7.25	7.4	7.6	8.1
Pocahontas semi-bituminous	1.30	1.40	1.55	1.70	1.95	2.70
Pittsburgh bituminous	0.60	0.72	0.82	0.90	1.00	2.05
Illinois bituminous	0.35	0.40	0.45	0.50	0.60	0.75
Lignite	0.20	0.20	0.25	0.25	0.25	0.40

The efficiency attainable with Pittsburgh coal is about 0.5% higher than with Pocahontas, and about 0.75% higher than with Illinois coal. Maximum attainable efficiencies with anthracite and Texas lignite are 5 to 6% lower than with Pittsburgh coal, while

they are but 2 to 2.75% lower with mechanically atomized oil. The attainable efficiencies with blast-furnace gas, and with coke-oven or natural gas are respectively 2 to 20% and 3 to 5% lower than with Pittsburgh coal. See Table 4.

The final cost of steam which determines the most economical fuel depends on: 1. Fixed operating and maintenance costs of boiler plant, exclusive of fuel and fan equipment. 2. Cost of fuel. 3. Fixed operating and maintenance charges on fuel storage, handling, preparation and burning equipment. 4. Fixed and operating charges on fans and draft equipment. 5. Fixed charges on plant capacities reserved to provide for peak requirements of fuel and fan equipment. Item (1) is common to all fuels; items (2) to (5) vary with each fuel.

Table 5 was derived from a study of the cost of operating steam plants designed to burn the fuels shown in the first column. The several columns of the table show the maximum price that can be paid for different fuels other than that for which it was designed if steam is to be generated at the same cost. The figures are absolute only for the conditions stated in the paper, but they will serve as a guide to the relative value of the various fuels when a choice is to be made of fuel in a primary design or it becomes necessary to change to a different fuel. In general, a plant designed for any solid fuel will be most economical when burning that fuel or any higher grade fuel obtainable at the same price per B.t.u. without additional capital expenditure. Some of the higher grade fuels may be more economical, even at a higher cost per B.t.u. A plant designed for a high grade solid fuel will not be economical, with a lower grade fuel. Thus a plant designed for lignite probably would prove more economical with Pocahontas or Pittsburgh coal, but if designed for these could not develop its required capacity with anthracite or lignite without additional capital expenditure. Pulverized solid fuels can compete with oil or natural gas, except in certain localities where oil or gas prices are low or where gas is a waste product.

SOLID FUELS

1. COAL

CLASSIFICATION OF COAL.—Coal is classified according to its percentage of fixed carbon and volatile matter as shown in Table 2. The progressive change from wood to the various grades of coal is shown in Table 1.

William Kent (*Trans.* A.S.M.E., xxxvi, 1914) developed the classification given in Table 2, in which the bituminous coals are divided into three grades according to the percentage of moisture in air-dried coal. The coals of highest inherent moisture also are highest in oxygen.

Table 1.—Progressive Change from Wood to Graphite

(J. S. Newberry in Johnson's Cyclopedia)

	Wood	Loss	Lignite	Loss	Bituminous	Loss	Anthracite	Loss	Graphite
Carbon.....	49.1	18.65	30.45	12.35	18.10	3.57	14.53	1.42	13.11
Hydrogen...	6.3	3.25	3.05	1.85	1.20	0.93	0.27	0.14	0.13
Oxygen....	44.6	24.40	20.20	18.13	2.07	1.32	0.75	0.75	0.00
	100.0	46.30	53.70	32.33	21.37	5.82	15.55	2.31	13.24

Table 2.—Classification of Coal

Class	Type of Coal	Volatile, percent of Combustible	Oxygen in Combustible, percent	Moisture in Air-dry, Ash-free Coal, percent	B.t.u. per pound of Combustible	B.t.u. per pound of Air-dry, Ash-free Coal
I	Anthracite..........	Under 10	1 to 4	Under 1.8	14,800 to 15,400	14,600 to 15,400
II	Semi-anthracite.......	10 to 15	1 to 5	" 1.8	15,400 to 15,500	15,200 to 15,500
III	Semi-bituminous......	15 to 30	1 to 6	" 1.8	15,400 to 16,050	15,300 to 16,000
IV *	Cannel..............	45 to 60	5 to 8	" 1.8	15,700 to 16,200*	15,500 to 16,050*
V	Bituminous, high grade	30 to 45	5 to 14	1 to 4	14,800 to 15,600	14,350 to 14,400
VI	" medium grade	32 to 50	6 to 14	2.5 to 6.5	13,800 to 15,100	11,300 to 14,400
VII	" low grade	32 to 50	7 to 14	5 to 12	12,400 to 14,600	11,300 to 13,400
VIII	Sub-bituminous; lignite	27 to 60	10 to 33	7 to 26	9,600 to 13,250	7,400 to 11,650

* Eastern cannel. The Utah cannel coal has a much lower heating value.

The U. S. Geological Survey (Bulletin 531) classifies coal as: 1. Anthracite. 2. Semi-anthracite. 3. Semi-bituminous. 4. Bituminous. 5. Sub-bituminous or black lignite. 6. Lignite. The differentiation of the several classes is by the fuel ratio, *i.e.* (fixed carbon ÷ volatile content). Fuel ratios are as follows: Anthracite, not less than 10; semi-anthracite, 6 to 10; semi-bituminous, 2.5 to 6; bituminous, 1 to 2.5. The sub-bituminous coals generally are black and shining, resembling bituminous coal, but having a lower calorific value. They weather more rapidly and have not the prismatic structure of bituminous coal. Lignite is brown in color, and has a woody structure. Its moisture runs from 30 to 40% higher than that of other classes of coal. Table 3 (Prof. N. W. Lord, *Power*, Aug. 18, 1908) gives analyses of representative coals of the six classes.

CAKING AND NON-CAKING COALS are classifications sometimes applied to bituminous coals. Caking coals soften under heat, and the pieces coalesce. These coals yield a compact, dense coke. Non-caking coals (also called free-burning) do not fuse, and the pieces preserve their form under heat. They produce a coke that is useful only when made from large pieces.

CANNEL COALS are bituminous coals with a higher hydrogen content than ordinary coals. They are used as enrichers in gas making. See Table 5.

GRAPHITIC ANTHRACITE is found in Rhode Island and eastern Massachusetts. It resembles anthracite and is burned with great difficulty. See Table 5.

Analyses and Heating Value of Coals

PROXIMATE ANALYSES determine percentages of moisture, volatile hydrocarbons, fixed carbon and ash in coal. See A.S.M.E. Test Code for Solid Fuels and A.S.T.M. Specification D271–33 for detailed instructions for making such analyses. The following paragraphs summarize these methods.

Moisture is determined by subjecting a sample of approximately 1 gram to a temperature of 220 to 230° F. Place sample in a porcelain or fused silica capsule, 1 3/4 in. diam., 7/8 in. deep, fitted with an aluminum cover, capsule and cover having been previously heated over concentrated H_2SO_4 for 30 min., cooled and weighed. Weigh sample, capsule and cover, place in a preheated (220 to 230° F.) oven, with cover removed and oven closed. Close oven and heat for 1 hr.; then cover capsules, cool in a desiccator and weigh. Loss of weight divided by weight of original sample is percentage of moisture in the coal. Air in the oven should be renewed 2 to 4 times per min., the air being dried by passing through concentrated H_2SO_4.

Samples are air-dried by spreading on tared pans and exposing to air at room temperature or at 18 to 27° F. above room temperature until loss of weight does not exceed 0.1% per hr. Ten-pound samples of dry or air-dried coal are crushed to pass a No. 20 sieve, sampled, reduced on a riffle to pass a No. 60 sieve. Moisture is determined on both No. 20 and No. 60 samples. Moisture in air-dried samples passing No. 20 sieve is corrected to total moisture as received. The following formulas will enable the analysis to be corrected to as received and dry-coal bases:

Air-dried to as-received

$$M_r = \{(100 - L_a)/100\}M_a + L_a$$
$$V_r = V_a\{(100 - L_a)/100\}$$
$$FC_r = FC_a\{(100 - L_a)/100\}$$
$$A_r = A_a\{(100 - L_a)/100\}$$

Air-dried to dry coal

$$V_d = V_a\{100/(100 - M_a)\}$$
$$FC_d = FC_a\{100/(100 - M_a)\}$$
$$A_d = A_a\{100/(100 - M_a)\}$$

M_r = total moisture as received; M_a = moisture in air-dry sample passing No. 20 sieve; L_a = air drying loss; V = volatile matter; FC = fixed carbon; A = ash; subscripts a, d, r = respectively, air-dried, dry coal, and as received; all quantities are in percent.

Volatile Matter is determined by heating a 1-gram sample in a platinum crucible, whose maximum and minimum dimensions are: diam., 35 and 25 mm.; height, 35 and 30 mm.; capacity, 20 and 10 cu. cm. The furnace should be a vertical electric tube furnace or a gas-fired muffle furnace, capable of regulation to maintain the temperature in the crucible at 1740 ± 36° F. Temperature determination is by a thermocouple in the furnace. Place the weighed covered crucible and sample in furnace, previously heated to 1740° F., and, after the more rapid discharge of volatile has ceased as shown by subsiding of luminous flame, expose to this temperature for exactly 7 min. Remove, cool and weigh. The loss of weight minus the moisture, divided by the weight of the sample is the percentage of volatile.

Ash is determined with the capsule and sample from the moisture determination. Place capsule and dried sample in a cold gas or electric muffle furnace, capable of temperature regulation between 1290 and 1380° F., and having good air circulation. Gradually heat to a redness at a rate that avoids loss from too rapid expulsion of volatile matter, and continue at a temperature between 1290 and 1380° F. until the weight is constant (± 0.001 gram). Stir ash with a platinum or nichrome wire before completion of test. Cool in a desiccator and weigh. Deduct weight of capsule, and divide by weight of original sample to obtain percentage of ash.

Fixed Carbon is determined from the previous determinations. Percentage of fixed carbon = (100 − % moisture − % volatile − % ash).

Sulphur is determined and reported separately. See reference above cited for methods.

Relative Value of Constituents.—The heating value of the fixed carbon in coal is about 14,600 B.t.u. per lb. That of the volatile matter depends on its chemical composition, varying with the district in which the coal is mined. In semi-bituminous coals, containing little oxygen, it may be as high as 21,000 B.t.u. per lb. In coals higher in oxygen, it may be as low as 12,000 B.t.u. per lb. The ash has no heating value. The moisture detracts from the heating value, as some of the heat of combustion of the fixed carbon and volatile matter is used to evaporate it and superheat the resultant steam to the temperature of the chimney gases.

THE HEATING VALUE OF COAL depends on its percentage of total combustible and the heating value per pound of the combustible. The latter is related to the percentage of volatile matter. It is highest in the semi-bituminous coals, being nearly constant at about 15,570 B.t.u. per lb. In anthracites, it ranges from 14,800 to 15,500 B.t.u., and from 13,000 to 15,500 B.t.u. in bituminous coals. It decreases with an increase of oxygen in the combustible. In lignites it may be as low as 10,000 B.t.u. per lb. The B.t.u. per lb. of combustible should be stated to permit comparison of different coals. Table 4, showing approximate heating value of coals in relation to volatile matter, was deduced by William Kent from Mahler's tests on European coals.

Table 4.—Approximate Heating Values of Coals

Percent Volatile Matter in Coal Dry and Free from Ash	Heating Value, B.t.u. per lb. of Combustible	Equivalent Water Evaporated, lb., from and at 212° F. per lb. of Combustible	Percent Volatile Matter in Coal Dry and Free from Ash	Heating Value, B.t.u. per lb. of Combustible	Equivalent Water Evaporated, lb., from and at 212 °F. per lb. of Combustible
0	14,580	15.09	32	15,480	16.03
3	14,940	15.47	37	15,120	15.65
6	15,210	15.75	40	14,760	15.28
10	15,480	16.03	43	14,220	14.72
13	15,660	16.21	45	13,860	14.35
20	15,840	16.40	47	13,320	13.79
28	15,660	16.21	49	12,420	12.86

The experiments of Lord and Haas on American coals (*Trans.* A.I.M.E., 1897) practically confirm these figures for all coals in which the percentage of fixed carbon is 60% and over of the combustible, but for coals containing less than 60% fixed carbon or more

(*Continued on p. 4-20*)

than 40% volatile matter in the combustible they are liable to an error in either direction of about 4%. It appears from these experiments that the coal of one seam in a given district has the same heating value per pound of combustible within 1 or 2% (true only of some districts), but coals of the same proximate analysis, and containing over 40% volatile matter, but mined in different districts, may vary 6 or 8% in heating value.

Table 5 is condensed from Bulletin 22, U. S. Bureau of Mines, the coals being classified in accordance with Table 2. The several coals given in the table can be compared on the basis of Col. 2, Table 7, by dividing the percentage of each constituent as given in Table 5 by (100−percentage of moisture). They can be compared on the basis of Col. 3, Table 7, by dividing the percentage of each constituent by (100 − percentage of moisture − percentage of ash).

Table 5 gives analyses of coals, also from Bulletin 22, U. S. Bureau of Mines, but which are not classified. The Rhode Island coals are graphitic and are not used as fuel. The volatile in the Alaska and Arkansas coals would class them as semi-bituminous, but they are higher in oxygen and moisture, and of lower heating value than the semi-bituminous coals. The Idaho coal apparently is a cannel coal but the ultimate analysis is lacking.

Evans's Equations.—The heating value of coal can be determined quite accurately from the percentage of volatile matter, provided the locality of the coal mine is known, as shown by F. C. Evans (Bull. No. 3, Cornell Univ. Engg. Expt. Station). Using the empirical relations given in Table 6, the heating value, hydrogen and carbon content of the combustible can be calculated. Thus the ultimate analysis of the dry fuel can be approximated from the proximate analysis, and then converted to the "as-received" basis by making the proper allowance for moisture. Sulphur may be assumed as from 0.5 to 2% in eastern coals, and as up to 8% in mid-western coals. Nitrogen will average about 1.25%, the range usually being from 0.75 to 1.75%. This table does not apply to lignites, peats, woods or cannel coal.

Table 6.—Empirical Relations for Coals of the United States

Based on Proximate Analyses.

Property of Coal Desired	States	Range of Volatile Matter in Combustible, Percent	Equation *
Heating value of the combustible	Pa., Ohio, W. Va., Md., Va., Ky., Ga., Tenn., Ala., Ind., Ia., Neb., Kan., Mo., Okla., Ark., and Texas.	0–16	$H.V. = 14{,}550 + 7{,}810\,V$
		16–36	$H.V. = 16{,}160 - 2{,}250\,V$
		36 up	$H.V. = 18{,}750 - 9{,}440\,V$
	Ill. and Mich.	All values	$H.V. = 16{,}062 - 3{,}830\,V$
Total carbon in the combustible	Penn., Ohio, W. Va., Md., Va., Ky., Ga., Tenn., Ala.	0–36	$C = 0.943 - 0.242\,V$
		36 up	$C = 1.095 - 0.663\,V$
	Ill., Ind., Mich., Ia., Neb., Kan., Mo., Okla., Ark. and Texas	All values	$C = 0.953 - 0.362\,V$
	Col., Utah, N. Mex., Ariz., Wyo., Mont., Wash., Ore. and Cal.	36–60	$C = \dfrac{(H.V. + 7{,}544)(0.0099 + 0.0208V)}{737.5\,V + 200}$
	All states	60 up	$C = \dfrac{(H.V. + 7{,}544)(0.0099 - 0.0045\,V)}{11.3\,V + 200}$
Hydrogen in the combustible	All states but Ark.	4–16	$H = 0.013 + 0.225\,V$
		16 up	$H = 0.0457 + 0.0206\,V$
	Ark.	All values	$H = 0.0327 + 0.056\,V$

* H.V. = high heating value of the combustible, B.t.u. per lb. V = fraction of volatile matter in the combustible. C = fraction of total carbon in the combustible. H = fraction of hydrogen in the combustible. Combustible = Coal − Ash − Moisture = C + V = Unity.

METHODS OF REPORTING COAL ANALYSES.—Three different methods of reporting coal analyses may be used as shown in Table 7. Combustible always is the sum of only the fixed carbon and volatile matter. Combustible often is called "moisture-free and ash-free coal." The method shown in column 2 of Table 4, percentages based on dry coal, is useful for comparing different lots of coal of the same class, and is better than the method in column 1, based on moist coal. Moisture is a variable constituent, depending on the weather, on condition of the atmosphere at the time of analysis and on the extent to which it accidentally may have been dried in sampling.

Table 7.—Methods of Reporting Analyses of Coal

	Moist Coal	Dry Coal	Combustible
Moisture	10	......	......
Volatile matter	30	33.33	37.50
Fixed carbon	50	55.56	62.50
Ash	10	11.11	......
	100	100.00	100.00

Factors Affecting Combustion of Coal

BURNING CHARACTERISTICS OF VARIOUS COALS (Henry Kreisinger and B. J. Cross, *Trans*. A.S.M.E. FSP-50-52, 1928).—Pennsylvania anthracite is used principally for domestic heating and in very small sizes under power plant boilers, either hand-fired or fitted with traveling grate stokers. It burns with a short, nearly transparent flame, due to burning of CO. Any desired rate of combustion can be obtained by regulating the flow of air. A few installations use pulverized anthracite. In this form it is difficult to ignite, and a small amount of air must be mixed with the coal to keep the temperature above the ignition point. A refractory front furnace wall assists ignition by keeping the incoming coal and air mixture above ignition temperature. Powdered anthracite burns with little visible flame.

Pocahontas semi-bituminous coal when burned on a grate tends to fuse and form a crust over the fuel bed, which must be broken by agitation to permit the flow of air. This coal is best burned in underfeed stokers. It pulverizes easily and burns with a short clear flame, comparatively free from smoke. The volatile is distilled off as permanent gases that do not break down to form soot. The fixed carbon residue is dense and burns slowly without visible flame. A large furnace volume is necessary to burn the carbon to ash. Pocahontas coal usually has a higher percentage of combustible in the flue dust than other bituminous coals.

New River coal is similar to Pocahontas in physical structure and its burning characteristics are similar. It is higher in volatile matter, has a very low ash content, and the highest heating value of any American coal.

The Eastern or Appalachian bituminous coals range in volatile matter from 28 to 35%. The Pittsburgh coals are representative. They are coking, and when burned on hand-fired grates or traveling grate stokers, tend to fuse and form a mass of coke. They are best burned in underfeed stokers. This type of coal does not pulverize easily. When pulverized, it burns with a long, luminous flame, which is smoky with inadequate air supply or inadequate mixing. Comparatively less of the coal is burned as fixed carbon, and there is less combustible in the flue dust than when burning Pocahontas or New River coal under similar conditions.

Illinois coals are free burning, *i.e.*, the pieces do not fuse together, but burn separately. They burn well on traveling grate stokers. The ash is more fusible than the ash of Appalachian coals, and agitation of the fuel bed produces clinker. The coal burns with a long luminous flame, and will produce smoke unless sufficient air is supplied over the fire and thoroughly mixed with the volatile matter as it is distilled. Illinois coal pulverizes more easily than the hard Appalachian coals, but not so easily as the Pocahontas type. When pulverized, it burns with a long, luminous flame. The fixed carbon usually is burned quite completely, and the flue dust contains from 5 to 3% of combustible.

Iowa coal is similar to Illinois coal, but is higher in moisture and ash, with a proportionately lower heating value. Kansas, Arkansas and Oklahoma coals also are similar to the Illinois coals, but contain less ash and moisture. They are free-burning and adapted to the traveling grate stoker.

Western sub-bituminous coals do not coke but burn freely, and have a tendency to crumble in the fire. They burn with a long yellow flame and are apt to produce smoke. These coals are soft and pulverize easily. When pulverized, complete combustion easily is obtained. The flue dust contains from 1 to 2% of combustible.

American lignites, when mined, usually contain from 35 to 40% moisture. They disintegrate to slack on exposure to air. In the fire the lumps crumble to pieces $^1/_8$ to $^1/_4$ in. diameter. The smaller pieces are carried out by forced draft, causing a high cinder loss. They burn with a long yellow flame which does not smoke as readily as the flame of bituminous coal. Lignites can be pulverized when the moisture is reduced to 28%, and complete combustion easily is obtained. The flue dust usually contains less than 1% of combustible.

Peat seldom is used as a fuel in the U. S. It is compressed into briquets and dried to a moisture content of about 20%. Peat burns with a long yellow flame similar to that

of lignite. The preparation of peat for the market is too costly to permit it to compete with good coal.

RELATION OF EXCESS AIR, RATE OF FIRING, RADIATION AND EMISSIVITY.—R. A. Sherman has made a laboratory study of the burning characteristics of pulverized Pocahontas, Hocking, Pittsburgh and Illinois coals (*Trans.* A.S.M.E. FSP–56–6, June, 1934). The characteristics of the coals were as follows:

	olatile	Fixed Carbon	Moisture	Ash	B.t.u. per lb.	Softening Temperature of Ash, deg. F.
Ohio, Hocking No. 6......	34.5	52.3	2.3	10.0	12,420	2590
W. Va., Pocahontas No. 3.	17.2	76.6	0.4	5.8	14,790	2630
Ill., No. 6...............	33.6	50.4	1.1	14.9	11,770	2250
Pa., Pittsburgh No. 8.....	40.0	50.2	0.5	9.3	13,200	1985

The study was to determine the relation of excess air to combustion of Hocking and Pocahontas coals, and for all four coals the relation of fineness of grinding to combustion, rate of firing and furnace temperature to completeness of combustion, and radiation and emissivity of flame to excess air, fineness and rate of firing. From curves in the paper the following data are taken: Relation of excess air to completeness of combustion (Table 8); relation of fineness of grinding to completeness of combustion (Table 9); comparative combustion temperatures, radiation and emissivity of the four coals (Table 10); relation of temperature and completeness of combustion to rate of burning (Table 11).

The study showed that unburned carbon continued to decrease up to 30% excess air with Pocahontas coal, and up to 20% with Hocking coal. Fineness of grinding is increasingly important as combustion space is restricted. The optimum limit of fineness differs for different coals. The rate of combustion varies for different coals. Pocahontas coal burns more slowly than any of the four tested. Illinois coal burns more slowly and Pittsburgh coal more rapidly than Hocking coal. Increased furnace temperature apparently increases rate of combustion. Ignition temperature and temperature in the ignition zone are important factors in the combustion zone. Curves for all the coals show a marked increase in the furnace temperature, a considerable decrease in unburned carbon, and a more rapid rate of combustion in the furnace after operating 7 hr. as compared with similar conditions after operating 2 hr. With respect to radiation, the study showed that temperature and total radiation of the flame were affected by fineness of grinding, excess air and rate of firing, but the emissivity of the flame at any one position was affected to a marked degree only by the type of coal. The emissivity of pulverized coal flames ranges from 0.7 to 0.3, decreasing as the carbon burns from the flame.

Coal Specifications

SPECIFICATIONS FOR PURCHASE OF COAL.—The following is an abstract of specifications and contract for coal for steam power plants, prepared by U. S. Bureau of Mines.

Description of the coal should include percentage of moisture in coal as received, and of volatile matter, ash, sulphur and B.t.u. per lb. in dry coal. The source of the coal should be given by naming the mines, their location and operators, and the name of the coal bed. The commercial name of the coal and the railroads on which the mines are located also should be given.

Comparison of Bids is on the basis of the cost of 1,000,000 B.t.u. The method is: 1. All coals are adjusted to the same ash percentage. That coal containing the lowest ash content is taken as the standard. The price quoted is multiplied by one-half the difference between the ash content of the standard and of any other offered coal; the product is added to the price of the non-standard coal.

2. The price as determined by (1) is divided by the difference between 100% and the percentage of moisture guaranteed. The result is computed to the nearest 0.1 cent. 3. The price as determined in (2) is multiplied by 1,000,000 and the result divided by (B.t.u. per lb. guaranteed) × 2240, or by (B.t.u. per lb. guaranteed) × 2000.

After eliminating undesirable bids, the selection of the lowest bid on the basis of the cost per 1,000,000 B.t.u. may be considered by the consumer as a tentative award. The consumer reserves the right to make tests or practical service tests to determine the final award.

Causes for Rejection are 3% more moisture, 4% more ash, 3% more volatile matter, 1% more sulphur or 4% fewer B.t.u. than the specified guarantees; or coal furnished from mines other than those specified, unless upon written consent of the consumer. The consumer has the option of either accepting or rejecting such coal. The consumer also may reject bids offering coals on which he has information that they possess undesirable physical characteristics, volatile matter, sulphur or ash contents; or because of clinkering or excessive refuse; or because they have failed to meet the requirements of city smoke ordinances; or for any other cause that would indicate them to be of a quality that renders them unsuitable for use in the consumer's storage or power plant equipment.

Price is adjusted for variations in heating value, ash and moisture content, from the guaranteed values, as follows:

1. On a "dry-coal" basis, the adjustment shall be proportioned to the variation in B.t.u. content from the guaranteed standard, when such variation exceeds 2%.

2. On a "dry-coal" basis, the adjustment for variations of more than 2% in ash content,

* Maximum temperature.

above or below the guaranteed standard shall be determined as follows: One-half the difference between the guaranteed ash content and the ash content as determined by analysis is multiplied by the bid price. The result is added to the price adjusted for B.t.u., if the ash content by analysis is below that guaranteed, or subtracted from it if the ash content by analysis is higher than the guaranteed content. Adjustment is to be figured to the nearest 0.1 cent.

EXAMPLE.—Guaranteed ash content, 10%; ash content by analysis, 13.25%; bid price, $3.00 per ton. Adjustment = (0.1325 − 10)/2 × $3.00 = 0.049 per ton deduction.

3. Adjustment for moisture in excess of that guaranteed is determined by multiplying the bid price by the percentage of moisture in excess of the guaranteed percentage, and dividing the product by 100.

EXAMPLE.—Guaranteed moisture, 3%; actual moisture, 4.58%; bid price, $3.00 per ton. Adjustment = (4.58 − 3) × $3.00/100 = 4.7 cents per ton deduction.

Miscellaneous Notes on Coal

ANTHRACITE SILT AND CULM is the product of the wet preparation of standard market sizes of anthracite. It ranges in size from 1/32 in. to dust, and was long considered a waste product. It, however, may be burned under boilers, either as pulverized fuel or in stokers, at a considerable saving in fuel cost. F. H. Dechant states that the design of the combustion chamber is an important element in burning it in stokers. The ignition arch should be short, and the rear arch long to prevent loss of unburned coal lifted from the grates. Baffles should be steeply pitched to prevent accumulation of fly ash. As a pulverized fuel it is best burned on the unit system, using a ball mill for pulverinzing. Data on installations using this fuel are as follows.

Plant No.	1	2	3	4	5	6	7	8	
Type of Stokers *	CG	C	H	C	C	C	C	..	M
Type of Pulverizer †	..	..	..	..	..	BM	..	BM	
Forced Draft, in. of Water	5	5	4	3	3	5	4		
Thickness of Fuel Bed, in.	6–8	6	5	5	5	6	5		

* CG = chain grate; C = Coxe; H = Harrington; M = Metropolitan; † BM = ball mill.

See also paper by F. S. Dechant, *Trans.* A.S.M.E., FSP-52-7, 1930.

SIZES OF ANTHRACITE AND SPACE OCCUPIED.—Table 12 gives the names and screen sizes of anthracite recommended by the Anthracite Operators Conference (now Anthracite Institute) 1929, and included in A.S.T.M. specification D310–31. The holes in the screens are round and staggered.

The space occupied by anthracite varies with the size of the coal. U. S. Bureau of Mines Bulletin 184 gives a table of various coals, from which the following figures are taken: Furnace, 52–55 lb. per cu. ft.; egg, 53–58 lb. per cu. ft.; chestnut, 52.5–56.5 lb. per cu. ft.; pea, 53.5-54.5 lb. per cu. ft.; No. 1 buckwheat, 50.5 lb. per cu. ft.

Table 12.—Screen Sizes of Anthracite

Size	Passes through	Retained on	Size	Passes through	Retained on
Broken	4 7/16 in.	3 7/16 in.	Pea	12/16 in.	8/16 in.
Egg	3 7/16 "	2 8/16 "	No. 1 Buckwheat	9/16 "	5/16 "
Stove	2 8/16 "	1 9/16 "	No. 2 " (Rice)	5/16 "	3/16 "
Chestnut	1 9/16 "	11/16 "	No. 3 " (Barley)	3/16 "	3/32 "

Screening affects the purity of the different sizes as regards ash. Table 13 shows the analyses of samples from one mine.

Table 13.—Effect of Screening of Anthracite upon Ash Content

Size	Screened		Analyses, percent	
	Through	Over	Fixed Carbon	Ash
Egg	2.5 in.	1.75 in.	88.49	5.66
Stove	1.75 "	1.25 "	83.67	10.17
Chestnut	1.25 "	0.75 "	80.72	12.67
Pea	0.75 "	0.50 "	79.05	14.66
Buckwheat	0.50 "	0.25 "	76.92	16.62

SPACE OCCUPIED BY BITUMINOUS COAL varies with the specific gravity of the coal, the relative proportions of lump and slack, the moisture content and the degree of settling to which it has been subjected The U. S. Bureau of Mines (Bulletin 184) reports a reduction in volume, due to shaking of the containers, of 4.2 to 8.34%. Table 14 shows the range of weights of bituminous and semi-bituminous coals given in Bulletin 184. The Bureau of Mines states that, other things being equal, the sample with the higher moisture content will weigh more per cubic foot and occupy greater space per

pound of dry coal than will a sample of lower moisture content. Increase in volume of wet coal is not proportionately as great as the increase in weight per cubic foot. Slack, comprising a mixture up to and including nut size, weighs more than screened nut coal.

MIXTURES OF HARD AND SOFT COAL for hand-fired boilers as shown in Table 17 are given in Tech. Paper 220, U. S. Bureau of Mines. The coking qualities of the soft coal prevent draft and grate losses of the fine anthracite, while the higher fixed carbon of the anthracite increases the heating value of the mixture.

Table 17.—Proportions of Soft and Hard Coal To Be Used for Hand Firing

		Soft Coal	Hard Coal
No. 1 Buckwheat	Forced draft	30%	70%
	Natural draft	40	60
No. 2 Buckwheat	Forced draft	40	60
	Natural draft	50	50
No. 3 Buckwheat	Forced draft	50	50
	Natural draft	65	35

WEATHERING OF COAL tends to effect a small decrease in heating value, and to produce mechanical disintegration when pyrites are present. Weathering of anthracite is confined to oxidation of the pyrites, but in coking coal it finally may destroy the coking power. Bulletin 136, U. S. Bureau of Mines, shows New River coal under outdoor exposure to deteriorate in heating value 1% in one year, 2% in 2 years and not over 3% in 3 years. Pittsburgh coal deteriorated 1.1% in 5 years; Pocahontas coal deteriorated 0.4% in 6 months and an additional 0.4% at the end of the second year. Illinois coal will deteriorate about 4% in storage. In a closed bin Wyoming coal deteriorated 4.57% at the end of 9 months and 5.26% at the end of 2 3/4 years.

Underwater storage of coal seems to prevent deterioration. S. D. Parr and N. D. Hamilton (Bulletin 17, Univ. of Ill. Engg. Expt. Station) conclude from experiments on 100 lb. samples: 1. [illegible] coal does not decrease appreciably in heating value. 2. Outdoor exposure causes a loss of heating value of 2 to 10%. 3. [illegible] advantage over open storage, except with high sulphur coals. 4. In most cases deterioration appears to be practically complete at the end of 5 months.

SPONTANEOUS COMBUSTION OF COAL is due to slow oxidation in an air supply insufficient to carry away the heat so formed. An ideal condition for spontaneous heating is mixed lump and fine coal, with a high percentage of dust, so piled as to admit a small amount of air. A high percentage of volatile does not of itself increase liability to spontaneous heating. The effect of moisture and sulphur is uncertain. Excessive moisture may cause fine coal to form a blanket, impervious to air, thus restricting the air supply to a point where spontaneous heating will ensue. The U. S. Bureau of Mines states that sulphur has only a minor effect, but a Nova Scotia coal containing 3 to 4% sulphur is reported to have given much trouble from spontaneous fires in storage.

The surfaces of freshly mined or freshly crushed coal oxidize readily. Such coal is quite liable to spontaneous heating in storage. In time, the surfaces are covered with oxide and tendency to heat is abated. If coal that has heated after six weeks or two months storage be rehandled and thoroughly cooled, it seldom will reheat spontaneously.

Tech. Paper 16, U. S. Bureau of Mines gives the following rules for storage of coal to avoid spontaneous combustion: Pile to a maximum depth of 12 ft., with no point in the interior over 10 ft. from an air cooled surface; if possible, store only in lump; reduce handling to a minimum to avoid dust formation; distribute lump and fine as evenly as possible; rehandle and screen after two months; keep away external sources of heat, as hot walls, steam pipes, oily waste, etc.; season coal six weeks after mining before storage; avoid alternate wetting and drying; avoid admitting air to interior of pile through interstices around timbers, irregular brickwork or porous bottoms (coarse cinders, etc.); avoid ventilation by pipes through the pile, which often is dangerous.

Coal should be so stored that its temperature can be ascertained daily. If the temperature rises to 160° F., a destructive temperature almost certainly will ensue, unless the warm coal is removed and cooled. See also Factors in Spontaneous Combustion of Coal, O. P. Hood, *Mech. Engg.*, Dec., 1923.

Ash

Fusibility of Ash.—Ash is a mixture of slate, clay, silica, iron oxide, lime, etc., each with a different fusion point, and all tending to react with each other under high heat to form slag. The temperature range of slag formation varies, depending on the composition of the ash, from 20 to 50° F. to over several hundred degrees. A high percentage of iron or lime causes the ash to melt at from 1800 to 2200° F., while high percentages of alumina and silica cause it to melt at from 2600 to 3000° F. The fusion of ash and formation of clinker were investigated by A. C. Fieldner, W. A. Selvig and P. Nicholls (*Trans.* A.S.M.E. FSP-50-6, 1928). Twenty-one samples of coal, as shown by Table 18 were studied. The analyses of the ash given are in Table 19. The fusion temperatures of the ash were determined by the standard method of the A.S.T.M. (A.S.T.M. Stds., 1924, p. 994). The softening temperature is that at which the test cone fuses down to a spherical lump. The fluid temperature is that at which the ash becomes fluid and spreads out in a flat layer. The study showed that the fusibility of ash depends on the ratio of the silica to the bases, the percentage of alumina, and on the bases present. Ash high in silica and alumina is not readily fusible and, usually, ash low in iron and lime have high silica and alumina. Coals high in sulphur generally will clinker readily.

The formation of clinker in relation to fusion temperatures also was studied. Due to the complexity of the reactions involved no absolute values can be given, but the following general conclusions seem to be true: Quantity of clinker formed decreases as rate of burning increases; density and fusion of the clinker is greater at the higher rates; the rate of decrease of quantity with rate of burning becomes less when ash fusion temperatures are low. The quantity of clinker has a definite relation to the softening temperatures of the ash. It decreases with increase of temperature and has small change for coals with

softening temperatures over 2600° F. The relation becomes more consistent as size of coal decreases. The washed coals (Nos. 9 and 20, Table 18) showed a reduction of clinker formation greater than that due to the proportion of inorganic matter removed.

2. PULVERIZED COAL

Pulverized coal is used for firing ing cement and lime in rotary kilns and other metallurgical furnaces. I· , as the heat libera- tion per cubic foot of combustior other method of burn- ing coal. Two general systems .em.

THE BIN SYSTEM

the furnaces.

The raw coal is crushed to a uniform › the pul may or not be dried before entering the claim drying is when the moisture does not exceed 4%. ..ed by the flue gases is used, being passed either through a coal dr· the pulverizer, reducing the moisture to about 2%. Fig. 1 from a paper by ... (*Trans.* A.S.M.E., FSP-53–4, 1931) comparing the performance of a boiler under bin and unit systems at the Calumet station of the Commonwealth Edison Co., Chicago, shows a diagrammatic arrangement of the bin system. For a complete description of the bin system, including various arrangements of equipment, see paper by Henry Kreisinger, *Trans.* A.S.M.E., FSP–52–36, 1930.

THE UNIT SYSTEM prepares the coal as required by the burners. One or more pulverizers are provided for each boiler, coal being fed directly to them from the slack coal bins. The coal is not dried before feeding to the pulverizers, but air heated to about 150° F. is blown into the pulverizer, dries the coal and blows pulverized fuel directly to the burner. At the burner, air from the air preheater, at 400 to 500° F. enters with the coal. While the capital investment is lower with the unit system, the capacity of the boiler is limited by the capacity of the pulverizer equipment, and shutting down the

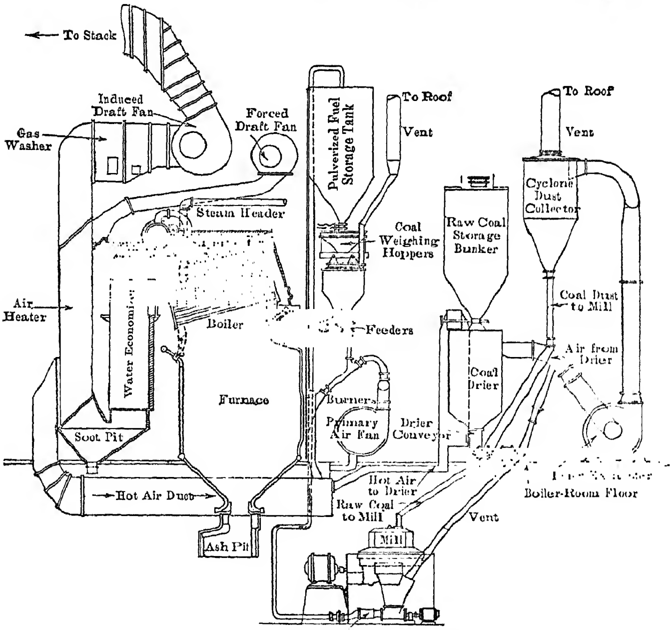

FIG. 1. Bin System of Pulverized Coal

pulverizer means shutting down the boiler also. Compensating advantages are that no storage of pulverized coal is required, eliminating explosion hazards. No preliminary drying of coal is necessary and the transportation system for coal is eliminated. Fig. 2 shows diagrammatically the boiler shown in Fig. 1 as rearranged for the unit system.

COMPARISON OF BIN AND UNIT SYSTEMS.—The equipment required for both bin and unit systems is shown in a paper by A. E. Grunert (*Trans.* A.S.M.E. FSP–53–4, 1931), comparing performance of a boiler of 5940 sq. ft. of heating surface with both bin and unit systems of firing. The equipment required for the bin system was: Raw coal storage bunker; air preheater, with induced draft fan; forced draft fans; gas washer equipment; coal dryer; dryer exhauster; cyclones; drag feeder; pulverizer; pulverized coal transport system; pulverized coal bunker; pulverized coal feeders; pulverized coal weigh bins and scales; a primary air fan; 8 burners. The equipment for the unit system for the same boiler was: Raw coal storage bunker; air preheater; induced draft fan; forced draft fans; air washer; raw coal scales; drag feeder; pulverizer; mill exhauster fan; 6 burners. The evaporative efficiency of the boiler was about the same under both systems, but the auxiliary power consumption of the unit system was lower. On the other hand, the maintenance and labor costs of the unit system were higher. There was but little difference in the total cost of steam generated by the two systems. In a report on pulverized fuel by the Prime-movers Committee of the National Electric Light Assoc., 1931 (now Edison Institute), a number of operating companies report experiences with both systems, tending to confirm the conclusions of Mr. Grunert. Reliability appears to be higher in the bin system while flexibility and efficiency are better with the unit system. Certain companies reported maintenance cost to be lower with the bin systems, while others reported it to be higher. In general, it would appear that so far as general operating characteristics are concerned there is but little to choose between the two systems, and the choice of one or the other should be based on local conditions.

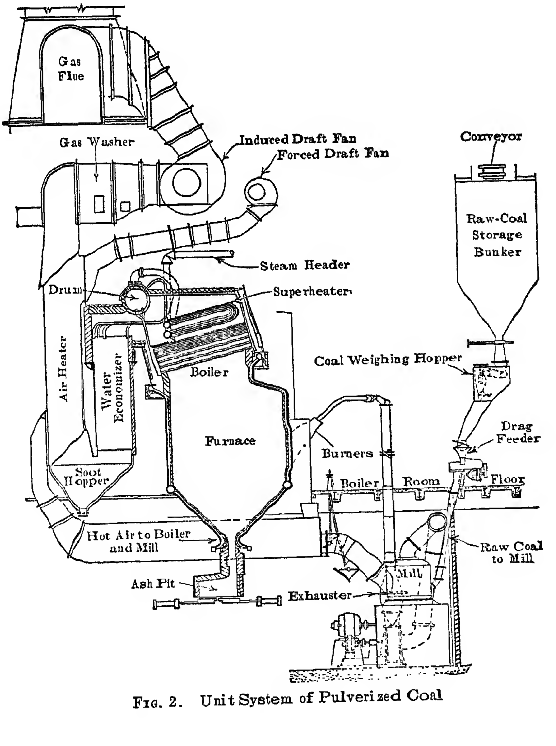

Fig. 2. Unit System of Pulverized Coal

BEST FINENESS OF PULVERIZATION.—The degree to which the coal is pulverized has a direct relation to the efficiency of the steam generating plant. The degree of pulverization varies with grade of coal and size of combustion chamber. If the fuel contains a considerable quantity of relatively coarse particles a larger furnace volume is necessary to permit these particles to be completely burned before striking the furnace walls. However, an excessive degree of pulverization increases the cost of coal preparation more rapidly than the corresponding saving due to increased boiler efficiency. E. H. Tenney (*Trans.* A.S.M.E. FSP–54–7, 1932) shows that with the coal used at the Cahokia Station of the Union Electric Light and Power Co., St. Louis, Mo., the maximum boiler efficiency was obtained when 75% of the coal passed through a 200-mesh screen, but that, due to the lower cost of pulverization, the total cost of steam was lowest when 57% of the coal passed through 200-mesh screen. Henry Kreisinger (*Trans.* A.S.M.E. FSP–54–9, 1932) gives the figures of Table 21 as the most economical fineness for various coals, considering the cost of pulverization and losses from incomplete combustion. Table 22 shows standard sieve sizes for fineness of powdered coal.

Table 21.—Economic Fineness for Various Coals

	Percentage passing through		
	200-Mesh	100-Mesh	50-Mesh
Anthracite	85	97	100
Eastern Low Volatile	75	92	98
Eastern High Volatile	65	85	97
Illinois	55	80	92
Sub-bituminous	45	75	90
Lignites	35	65	88

Table 22.—Standard Sieve Sizes for Fineness of Pulverized Coal

Sizes		Sieve Opening, in.	Wire Diam., in.	Tolerances, percent			
U. S. Standard Sieve Series No.	Microns			In Average Opening	Wire Diam. Under	Wire Diam. Over	In Maximum Opening
16	1190	0.0469	0.0213	± 3	15	30	10
30	590	.0232	.0130	± 5	15	30	25
50	297	.0117	.0074	± 6	15	35	40
100	149	.0059	.0040	± 6	15	35	40
200	74	.0029	.0021	± 8	15	35	60

To determine the fineness of coal delivered by the pulverizers, sampling of the coal stream in the feeder ducts is necessary. The A.S.T.M. tentative standard calls for a thin-walled brass elbow moved through a stuffing box uniformly across the diameter of duct. The accuracy of this method has been questioned, as in horizontal ducts heavier particles tend to flow along the bottom of the duct and do not redistribute themselves uniformly in vertical ducts. The Duquesne Light Co., Pittsburgh, Pa., collects samples in a quart Mason jar moved across the cross-section of a vertical duct connecting the bottom of the cyclone separators with the storage bin. The Detroit Edison Co. has found a double-barreled thief sampler, so arranged that the open slot can be closed before removal from the coal stream, to be satisfactory. Prof. W. A. Willis (*Power*, Dec. 18, 1928) has developed a method of taking samples from the coal and air stream in the duct between pulverizers and burners, 4 ft. above the fan, in which he placed the opening of the sampler 7 1/2 in. from one end on the center line of the duct, and obtained samples of the same fineness as were obtained by a traverse of the duct in twelve equal areas. Horace C. Porter (*Trans.* A.S.M.E. FSP–52–16, 1930) discusses various methods of sampling and gives the following as essential for securing good samples: Samples should be taken from a vertical duct, if taken from the air-coal stream. They should be taken at least 10 ft. away from an elbow, branch or other irregularity, and as far away as possible from disturbing action of fans or blowers. A stuffing box should be used through which a sampling pipe with a right-angle bend facing the air stream and without irregularities on its inner surface, can be moved freely, which tube should be moved systematically to different positions in the cross-section of the duct to correspond in its time schedule with known variations in density of the coal-air mixture. Samples should be taken at several different places in the piping system and mixed to obtain an average.

VELOCITY OF PARTICLES IN FURNACE.—Air velocity in the furnace should be such as to carry the fuel particles in the air stream until they are consumed, otherwise the coarser ones will fall to the bottom of the furnace unburned, with a resulting uncon-d carbon loss. The rate of fall of particles of fuel in still air varies with the diam-

eter. E. G. Bailey (*Trans.* A.S.M.E. FSP-50-72, 1928) presents a curve showing the velocity of fall for various diameters of particles as follows:

Diameter, in......	0.001	.002	.003	.004	.005	.006	.007	.008	.009	.010	.011
Velocity, ft. per sec.	0.16	0.48	0.93	1.41	2.14	3.10	4.19	5.48	6.97	8.48	10.2

The vertical velocity of the gases in the furnace must be higher than the figures above given if the particle is not to fall out of the air stream. R. A. Sherman (*Trans.* A.S.M.E. FSP-54-7, 1932) points out that these figures should not be applied to horizontally moving gases. For horizontal movement of gases the terminal velocity of the particle as above given is the downward component of movement, and should be used as such in calculating the velocity required in ducts and furnaces. See also analysis of this subject by John Blizard, *Jour.* Franklin Inst., vol. 197, 1924.

RATE OF COMBUSTION AND IGNITION TEMPERATURES.—The rate of combustion depends on the character of fuel, the temperature of the furnace and the size of the particles. Volatile matter is consumed rapidly, and the fixed carbon more slowly. Hence, high volatile fuels tend to burn at a higher rate than low volatile. The relation between furnace temperature and rate of combustion is discussed by Griffin, Adams and Smith (*Indust. and Engg. Chem.*, Sept., 1929). They present curves from which the following figures are taken:

Furnace temperature, deg. F...	1300	1400	1500	1600	1700	1800
Size			Time, milli-seconds			
−80 + 90 mesh..............	100	125	145	170	185	205
−50 + 60 "	....	285	330	370	415	455
−45 + 40 "	....	320	385	440	500	560

It should be noted from the above figures that the higher the furnace temperature the slower the rate of combustion. Several theories have been advanced to account for this negative temperature coefficient. See paper by E. H. Tenney (*Trans.* A.S.M.E. FSP-54-7, 1932), which discusses rate of combustion. Mr. Tenney states that the rate of delivering air to the particle of fuel is probably more important than combustibility of the fuel, and since combustion occurs only at the surface of the particle the advantage of great fineness is evident. As each particle of coal dust requires for complete combustion 35,000 times its volume of air, the quick dispersion of the coal particles into the centers of such spheres of air is important, and requires considerable turbulence, which is increased with excess air. Turbulence further scrubs away products of combustion and facilitates delivery of fresh air. Henry Kreisinger (*Trans.* A.S.M.E. FSP-54-9, 1932) also discusses this subject and develops an equation for the rate of contact between oxygen and combustibles. He concludes that intensive mixing in the furnace is the most important factor for producing rapid combustion.

The combustion chamber temperature necessary for the ignition of fuel varies with fineness of the coal. E. H. Tenney (*Trans.* A.S.M.E. FSP-54-7, 1932) shows this relation for one kind of coal to be as follows:

Diameter of particle, in..........	up to 0.002	0.003	0.004	0.0045
Furnace temperature, deg. F......	1300	1500	1900	2200

It should be noted that the above are furnace temperatures and not the ignition temperatures of the fuel.

HEAT LIBERATION.—The rate of heat liberation per cu. ft. of furnace volume per hour with pulverized fuel should not exceed 20,000 B.t.u. with refractory furnaces under continuous operation. Where the ash is fusible, a rate of 15,000 B.t.u. usually is the maximum that should be attempted. Water-cooled furnaces will permit a rate of 30,000 B.t.u. for continuous operation and a peak rate of 35,000 B.t.u. (Henry Kreisinger, *Trans.* A.S.M.E. FSP-54-9, 1932). These figures are in excess of those usually reached in practice. A study of operating practice of 250 central stations, by the Central Station Committee of the Power Division of the A.S.M.E. (C. F. Hirshfeld and G. U. Moran, *Trans.* A.S.M.E. FSP-55-8, 1933) shows the following heat outputs in superheated steam B.t.u. per cu. ft. of furnace volume per hr.: Water-cooled furnaces, maximum, 21,800; minimum, 8100; average, 13,084; air- and water-cooled furnaces, maximum, 12,300; minimum, 7000; average, 9114; air-cooled furnaces, maximum, 13,700; minimum, 5900; average, 8992. Boiler efficiencies are not given in the report, but assuming that the maximum efficiency is only 75%, the heat liberations per cu. ft. of furnace volume would be as follows: Water-cooled furnaces, maximum, 29,065; minimum, 10,800; average, 17,445; air- and water-cooled furnaces, maximum, 16,400; minimum, 9330; average, 12,150; air-cooled furnaces, maximum, 18,266; minimum, 7865; average, 11,989.

COMPLETENESS OF COMBUSTION varies with furnace temperature, fineness of grinding and excess air. See Burning Characteristics of Coal, p. 4–21.

METHODS OF FIRING.—The three general systems of firing pulverized coal are vertical, horizontal and tangential. Modifications of these systems also are used.

The Vertical System fires the coal-air mixture vertically downwards. Burners are located in the arch of the furnace. Primary air enters through the burner and secondary air through ports in the front wall. The two streams impinge at right angles, causing turbulence and mixing. The coal-air mixture takes a U-shaped path through the fur- : the bottom and flowing up through the boiler tubes. Secondary air f 1 to 2 in. of water. Comb

angle.

The Horizontal System fires the fuel and primary air through burners wall of the furnace. The secondary air may be preheated and is supplied sure through the burner. Both primary and secondary air streams are caused to rotate as they leave the burner to intensify mixing and tubulence. A modification of the horizontal is the double opposed system. Rows of burners are placed in opposite walls of the furnace. The coal-air streams impinge at the center, producing high turbulence and xing.

gential System uses four burners, one in each corner of the furnace and in located that the coal-air streams are tangent to the length of one side of the furnace. The four streams impinge on each other at right angles, with resulting violent turb the mixture completely filling the furnace. High rate of heat liberation thus is obtained. From 25 to 50% of the air supply is primary air. The balance is supplied under pressure through the burner around the coal nozzle This system is applicable only to completely water-cooled furnaces.

COAL PULVERIZERS reduce the coal to the desired fineness either by impact or attrition. The impact mill comprises a series of hammers mounted on a shaft. When apidly revolved the hammers break the coal up to the desired degree of fineness. The n mill crushes the coal between balls or rolls and stationary or revolving rings. Typical machines of the two types are described below. Approximate dimensions, capacity and power consumption are given in Tables 23 to 25. In using these tables, it should be noted that capacity, power required, and degree of pulverization will vary with every grade of coal, and the figures are for general guidance only.

Impact Mills.—The Raymond mill, Fig. 3, and Table 23 is a typical impact machine. Swinging hammers *A* on the shaft *B* crush the coal as it is fed from the feeder *C*. The pulverized coal is drawn through the conical outlet *D* by the exhaust fan *E*, whence it is delivered to storage bin or coal burner. The deflector *F* on the shaft *B* rejects the coarser particles and returns them to the hammers for further pulverization. The degree of fineness can be regulated by moving *F* axially along the shaft.

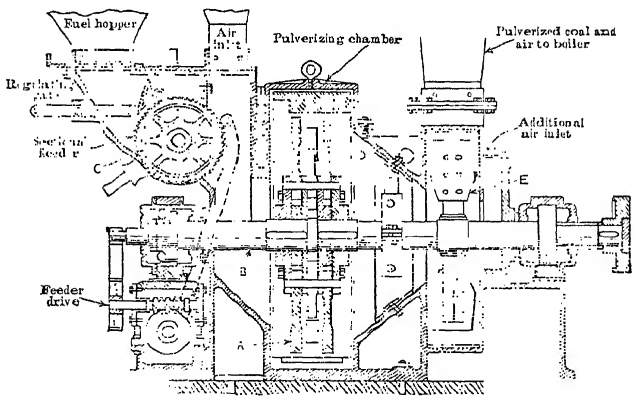

FIG. 3. Raymond Impact Pulverizer

Table 23.—Dimensions and Capacities of Raymond Impact Mills

(Combustion Engineering Corp., New York, 1935)

Capacities are based on fineness of 65% through 200-mesh screen. Power requirements include power for both mill and exhauster.

Attrition Mills pulverize the coal by balls or rollers. Fig. 4 shows a Babcock & Wilcox pulverizer. Two rows of balls *A*, 9 in. diam., are interposed between the stationary rings *B* and *C*, and the rotating ring *D*. Ring *D* floats on and is driven by the main shaft *E*, and in turn propels the balls *A*. Grinding pressure is applied by springs *F* which bear on ring *B*. Coal is fed through the inlet *G* and passes successively through the two rows of balls. Air blown through *H* carries the pulverized coal through the cyclone *J*, whence it passes through the outlet *K* to storage bin or burner.

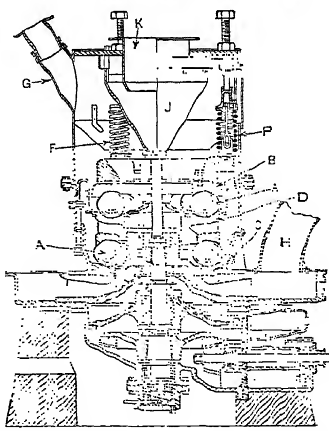

FIG. 4. Babcock and Wilcox Pulverizer

The Raymond roller mill, Fig. 5 and Table 24, comprises a series of vertical rollers *A*, carried on a spider *B*, which is rotated by the shaft *C*. The roller supports are pivoted on the spider at *D*, so that under the influence of centrifugal force they swing out against the bull-ring *E*. Coal enters from feeder *F* and is pulverized between rollers and bull-ring, falling to the bottom of the mill where it is plowed into the currents of entering air by plows *G*. Air blown in from windbox *H* enters the mill through tangential ports in the base casting *J*. The air carries the pulverized coal up to the outlet, first passing it through the separator *K* which rejects

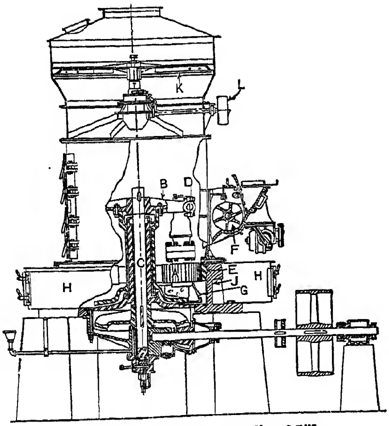

FIG. 5. Raymond Roller Mill

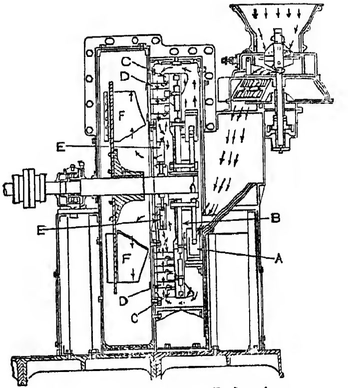

FIG. 6. Riley Atrita Pulverizer

coarse particles and returns them to the rollers. The degree of fineness is governed by the speed of the deflector, which is driven from L through a variable speed transmission.

Combination Impact and Attrition Mill.—The Riley Atrita pulverizer, Fig. 6 and Table 25, is a combination impact and attrition machine. Raw coal from the feeder flows into the first compartment where swing hammers A, carried on the rotor B, reduce it to a granular state by impact. The partially pulverized coal passes around the rotor and is ground by attrition between the pegs C on the rotor and stationary pegs D on the housing. The fuel is drawn through rejector arms E, by the fan F. The heavier particles are thrown out of the rejector by centrifugal force and returned for further attrition.

THE GRINDABILITY OF COAL is an important factor in selecting coal for pulverized fuel installations. Relative grindability may be expressed as the ratio of the total increase of surface produced by grinding to the surface of a standard sample subjected to similar treatment. R. M. Hardgrove (*Trans.* A.S.M.E., FSP-54-5, 1932) describes methods of determining grindability. The original sample consists of material that passes a 16-mesh screen and is retained on a 30-mesh screen. After grinding, the sample is passed through the screens of Table 26. The surface units of the ground sample are calculated by multiplying the percentage remaining on each screen by the surface factor, *i.e.*, the reciprocal of the average opening as given in Table 26. An arbitrary factor of 1000 is used for all material passing 300 mesh. A typical calculation of the grindability of Illinois coal, ground in a ball mill is as follows:

Screen Mesh	Percentage between Screens		Factor		Surface Units
16– 30	24.4	×	29		708
30– 60	36.0	×	61		2196
60–100	13.8	×	129		1780
100–140	7.2	×	202		1454
140–200	3.8	×	285		1084
200–230	1.6	×	377		602
230–300	2.4	×	465		1116
Through 300	10.8	×	1000		10800
			Total surface units	=	19740
			Surface units of original sample	=	2900
			New surface units	=	16840

New surface units of standard sample = 29,961; grindability relative to standard sample = 16,840/29,961 = 56.2%.

This method is based on Rittinger's law that the work done in grinding is proportional to the new surface produced. The grindability of a coal appears to have a relation to its volatile content. Coals of from 16 to 28% volatile have high grindability, this decreasing with increase of volatile. The volatile content cannot, however, be taken as an

index of grindability. Furthermore, the grindability depends to some extent on the apparatus used to determine it, and on the operating speed. Hardgrove used a ball mill, a mortar and pestle and a tube mill machine. The first two gave fairly consistent results, while the third was so erratic that its results were not comparable. Consistent results were obtained when the ball mill operated at 60 r.p.m. and the mortar and pestle at 1300 strokes per min. The relation between grindability and pulverizer capacity must be determined for each type of pulverizer and the conditions under which it operates.

Table 27 condensed from Hardgrove shows the grindability of a variety of coals. Table 28 shows the grindability of various cokes. See also paper by H. J. Sloman and A. C. Barnhart, *Trans.* A.S.M.E., FSP-56-13, Oct., 1934.

EXPLOSIONS AND FIRE HAZARDS OF PULVERIZED COAL.—A mixture of 30% pulverized coal dust and 70% finely powdered shale is explosive (Bull. 242, U. S. Bureau of Mines, 1925). Hence, coal dust which may have settled on floors and girders of industrial plant buildings is not made inert by the incombustible material mixed with it. Dust collected from the interior of buildings housing furnaces using pulverized coal often contains as high as 23.5% volatile matter. Coal dust containing 10 to 15% volatile matter is explosive.

Spontaneous combustion probably causes most of the fires in storage bins. Experiments by Porter and Ralston (U. S. Bureau of Mines) showed that oxidation of coal increased rapidly at about 150° F. If coal is stored at a fairly high temperature in the presence of sufficient air, the oxidation will raise the temperature to the ignition point. Overheating of coal is especially liable to occur in direct heat driers. The gases of combustion should not be allowed to become so hot as to overheat the coal. Storage bins should be so located that they will not become heated by steam pipes or hot flues.

After a shut-down, delivery of coal from the storage bins should not be allowed until it is certain that the coal has not been heated to a point where it will ignite when brought in contact with air. Fires occur in distribution lines due to back-fires from the heated furnace, caused by air pressure in the distributing line dropping below the secondary air pressure.

When the plant shuts down all furnaces should be cut from the supply line, the gate from the pulverized fuel bin closed, and the transport line blown out free from pulverized coal. In examining bins and other storage places where coal dust may exist open lights should not be used. Electric bulbs should be protected from breakage, as coal dust may be ignited by the hot filament of the lamp.

The maximum quantity of pulverized coal that can be stored, according to the rules of the National Fire Protection Association, is as follows:

Temperature of coal entering mills, deg. F........	250	225	200	175	150
Maximum stored quantity, hours supply for plant.	4	8	12	16	18

FLY ASH FROM PULVERIZED FUEL.—Removal of fly ash from the gases of combustion of boiler plants using pulverized fuel often is necessary to avoid creating a nuisance. Several methods are used: 1. Separators of the cyclonic type, which eliminate the dust by centrifugal action. 2. Separators with baffles that cause abrupt changes of direction of the gases and trap the dust in the baffles. 3. Separators using fans, that throw the dust, by centrifugal action to the periphery of the scroll. 4. Electric precipitation of the dust. 5. Removal of dust by water sprays.

The efficiency of the several methods depends on local conditions. Some factors affecting efficiency are the volume, temperature, relative humidity, chemical analysis and velocity of the gases, the quantity of dust per unit of gas volume, the relative proportions of coarse and fine dust. Comparisons of relative efficiency of different methods of separation, therefore, is useless unless all conditions are known.

Fineness of dust has a marked effect on the dust recovery effected in the separator. The efficiency of a cyclone type separator has ranged from 60% where over 50% of the dust passed a 300-mesh sieve, to 99% where over 90% of the dust passed through 300-mesh. For equal efficiency, the velocity of gas required for the finer dust is about double that required for the coarser. Other types of separators show about the same range of efficiency with variation in dust content, fineness, etc. The manufacturers of equipment should be consulted in regard to selection of equipment to meet any given set of conditions. See paper by K. Toensfeldt (*Trans.* A.S.M.E., FSP–50–59, 1928), for a description of the various systems and results of tests.

The recovery of fly ash from a 12 ft. diam. stack by means of water sprays is described by J. W. Mackenzie (*Trans.* A.S.M.E., FSP-53-5, 1931). The nozzle was located about 20 ft. above the breeching, and required about 30 gal. of water per min. at 10 lb. pressure. A second nozzle 15 ft. above the first, directed its spray upward. The percentage of fly ash to coal fired ranged from 5.63 to 11.16%, and the ash recovered ranged from 46 to 31%. An acid-resisting lining for the stack was necessary.

3. LOW TEMPERATURE CARBONIZATION OF COAL

Low temperature carbonization comprises essentially the destructive distillation of coal at temperatures of not over 1500° F. Its object is to provide a cheap fuel by removing from coal its more valuable constituents as tar, light oils and rich gas, and also to enable bituminous coal to be used as a substitute for anthracite as a domestic fuel. The products of low-temperature distillation are a semi-coke, containing sometimes as high as 15% volatile matter, tar, light oils and gases high in hydrocarbons. The gases most profitably may be used as enrichers for producer water gas. Low temperature carbonization processes have been developed to a considerable extent in Europe, but plants in the U. S. have until now (1935) been largely experimental. The coal used generally is a coking coal, since non-coking coals do not yield the same value in by-products and require special prior processing to produce lumpy coke. A number of low-temperature carbonization processes are described in the Proceedings of the International Conference on Bituminous Coal, Pittsburgh, 1928.

THE CARBOCITE PROCESS treats the coal continuously in slightly inclined rotary furnaces. The coal is crushed, dried and heated to 450° F. in a primary drum, and then distilled at 900–950° F. in a secondary drum or carbonizer. Each drum comprises concentric shells with an annular space 2 in. wide between them, through which flow the heating gases. At a test plant at Philo, Ohio, the coke from West Virginia coal contained about 12% volatile, was dense and strong, and ranged in size from 1/4 to 4 in. diameter. The gas had a heating value of about 800 B.t.u. per cu. ft.

THE TRUMBULL PROCESS comprises a series of retorts heated by superheated steam. The coal is preheated and dried by waste gases from the boiler and superheated, and then is fed intermittently to the retorts, set in batteries of two. The superheated steam passes successively through the several batteries of retorts, being resuperheated between each battery, the temperature being somewhat lower in successive batteries.

THE PLASSMANN PROCESS developed to carbonize low-temperature slightly coking coals, utilizes a vertical retort. The coal is subjected to pressure which is varied according to the compactness of coke desired.

THE TURNER PROCESS uses a vertical retort, with highly superheated exhaust steam as the heating medium. Steam is admitted at the bottom of the retort, which is charged and discharged continuously through valves. Gas is discharged through valves that operate between two fixed pressures, and is condensed in a tubular condenser. The experimental fuels comprised peats, lignites, oil shales, cannel and bituminous coal. The latter presented some difficulties, some requiring treatment for 12 hr. The yield of coke is about 70% by weight. The following yields of oil have been obtained per ton: From peat, up to 20 gal.; from lignite, up to 61 gal.; from oil shale, up to 80 gal.; from bituminous coal, up to 45 gal. One ton of steam at 1200° F. was required to treat 1 ton of bituminous coal.

THE WEISS SYSTEM for low temperature distillation of briquets uses superheated steam at about 1200° F. Coal dust is formed into briquets, with pitch or asphalt binder. The retorts, of 20 tons capacity, are heated progressively with the superheated steam, which then is condensed to recover the primary oils, tars and gases.

THE K. S. G. PROCESS, for the production of domestic fuel (*Trans.* A.S.M.E., FSP–50–28, 1928), utilizes two inclined concentric retorts which rotate as one. Coal is dried at about 400° F. as it passes through the inner retort. It then is fed into one end of the annular space between the two retorts and is discharged as coke at the opposite end. The gases of combustion from the furnace surround the outer retort. Superheated steam is admitted into the coal charge in the zone of highest temperature to prevent carbon deposits and to depress the vapor pressure of the tar as it is formed, thereby reducing thermal decomposition of the tar. By mixing gases of combustion with flue gas at 600° F., recirculated from the base of the stack, four temperature zones surrounding the outer retort are formed, with temperatures of 1320°, 1300°, 1000° and 1000° F. respectively.

Coal containing from 3 to 4% moisture, and of proximate analysis: volatile matter, 23 to 25%; fixed carbon, 59 to 63%; ash, 13 to 17%; calorific value, 12,000 B.t.u. per lb., yielded, per ton (2000 lb.) by weight, coke (12% volatile), 84%; gas, 2000 cu. ft., 5.5%; tar, 14 gal., 6.2%; light oil, 2.5 gal., 0.8%; moisture, 3.5%. The gross heat necessary to carbonize 1 ton of coal was 1,630,000 B.t.u. and 35 I.Hp. was required to drive the apparatus. The coke recovered easily ignites, is free burning and smokeless. A typical screen analysis is: 1 1/2 in. and over 32%; 3/4 to 1 1/2 in., 36%; 1/2 to 3/4 in., 11.8%; 1/4 to 1/2 in., 13.9%; 0 to 1/4 in., 6.3%. The tar recovered has a specific gravity of 1.05 to 1.06 at 60° F. The specific gravity of the light oil recovered is 0.775 at 60° F. Table 29 gives typical distillation analyses of tar and oils. Gas recovered from the same coal from which the foregoing tars and gas were formed analyzed: CO_2, 4.5%; C_nH_m, 5.2%; O_2, 1.6%; CO, 5.9%; H_2, 15%; C_2H_6, 6.3%; CH_4, 46.7%; N_2, 14.8%. Its specific gravity was 0.696 at 60° F.; gross heating value, 814 B.t.u. per cu. ft.; yield, 3200 cu. ft. per ton of 2000 lb.

Table 29.—Distillation Analyses of Tar and Light Oils from Low-temperature Coal Carbonization

ECONOMICS OF DISTILLATION OF POWER PLANT COAL.—In a circular, Distillation Products of Coal (Natl. Elec. Light Assoc., now Edison Institute, 1929), the Babcock and Wilcox Co. contributes an analysis of the cost of developing power in

the ordinary steam power plant, and one using coke produced by low temperature distillation, credit being given in the latter case to the value of the by-products from carbonization. The conditions assumed were a plant of 25,000–75,000 kw. capacity, operating at an annual average load of 40% of capacity, using coal of 12,722 B.t.u. per lb. The total power cost was 1.16 cents per kw-hr. The analysis shows that if the carbonization process can be operated at a cost of less than 3 cents per 1,000,000 B.t.u. in coke delivered as a boiler fuel, all fixed charges included, the process will be profitable; otherwise it will be unprofitable when operated as an auxiliary. The statement is made that a coal process will pay, under the assumed conditions, when the sum of its operating and investment increments of cost is equal to or less than 22% of that of the boiler plant in dollars per year. This percentage will vary with conditions other than those assumed in the analysis.

LOW TEMPERATURE CARBONIZATION OF SOUTHERN APPALACHIAN COAL.—Leo Holdridge (*Trans.* A.S.M.E., FSP–51–43, 1929) describes laboratory tests on a coal of analyses: Ash, 6.56%; moisture, 1.68%; volatile, 35.71%; fixed carbon, 56.65%; heating value, 13,916 B.t.u. per lb. The coal was carbonized at a maximum temperature of 1000° F. The yield per ton of coal was: Semi-coke, 1393 lb.; gas, 3613 cu. ft.; dehydrated tar, 37 gal. The tar products per ton of coal were: Motor fuel, 18,480 B.t.u. per lb., 4.4 gal.; burning oil, 18,172 B.t.u. per lb., 4.6 gal.; light lubricating oil, 4.4 gal.; heavy lubricating oil, 2.8 gal.; grease, 12 lb.; pitch, 90 lb.; tar acids, 66 lb. The properties of the dehydrated tar are given in Table 30.

Table 30.—Properties of Dehydrated Tar

	Dehydrated Tar	Dehydrated Tar, Less Oils to 212° F.	Dehydrated Tar, Less Oils to 447° F.	Pitch at 554° F.	Pitch at 617° F.

4. COKE

Coke is formed by distilling the volatile matter from coal. Gas coke is formed in a gas-works retort. Oven coke is made in a coke oven, either of the beehive or by-product type. But little beehive coke is now (1935) made. Gas coke is unsuitable for metallurgical purposes, but is used as a domestic fuel. Table 31 from Bulletin 6, U. S. Bureau of Mines, gives analyses and heating values of cokes and the coal from which they were made. Oven coke is used principally as a metallurgical fuel. It has a hard, close texture, is porous and brittle. It retains moisture in quantities up to 20%.

* Condition—A = 3 days after quench; B = from retorts.

THE HEATING VALUE OF COKE may be calculated roughly from the formula $H = \{14{,}600\,(100 - A)\} \div 100$, where H = heating value, B.t.u. per lb.; A = percentage

of ash. The yield of coke varies widely with different coals, ranging from 90 to 35% of the weight of the coal. Tables 32 and 33, Bulletin 50, U. S. Bureau of Mines, gives the range of analyses of beehive and by-product coke from several localities. Table 34 (Tech. Paper 367, U. S. Bureau of Mines) gives the analyses and heating values of three samples of Clairton (Penn.) by-product coke, weighing 33 lb. per cu. ft.

3	0.8	1.1	80.5	17.6	11,720	14,370

BY-PRODUCTS RECOVERED IN COKE MANUFACTURE.—A typical yield of a by-product coke oven per ton of coal charged is: Coke, 73–74%; tar, 4–6%; ammonium sulphate, 1–1.25%; gas, 10,000 cu. ft. The coal tar is split into light and heavy oils and pitch. The tars are the bases of many dyes, medicinal preparations and other industrial products. See also Low Temperature Carbonization of Coal, p. 4–37.

COKE BREEZE is fine coke, 1/2 in. and smaller. Tech. Paper 303, U. S. Bureau of Mines, gives the typical analysis of a by-product coke breeze shown in Table 35. A stack draft of 0.5 in. of water was required to burn a mixture of this breeze, both coarse and fine, with bituminous coal, when burning 8 to 11 lb. per sq. ft. of grate per hour.

Table 35.—Analyses of Coarse and Fine Coke Breeze

COKE AS A DOMESTIC HEATING FUEL is discussed in U. S. Bureau of Mines Report of Investigation 2980. Coke of 1 1/2-in. mesh screen size appears to be the most satisfactory, with draft above the fire ranging from 0.02 in. of water when burning 1 lb. per sq. ft. of grate per hr., to 0.09 in. when burning 8 1/2 lb. per sq. ft. per hr.

PETROLEUM COKE, used for carbon electrodes and dry cells, is the residue remaining after refining crude petroleum. It has a range of analysis of about: Fixed carbon, 90–95%; volatile matter, 5–10%; ash, up to 1.5%; sulphur, 0.1 to 0.5%.

LOW TEMPERATURE COKE is produced by carbonizing coal at temperatures below 1400° F. See Low Temperature Carbonization of Coal, p. 4–37.

DRY-QUENCHED COKE, that is, glowing coke quenched without the use of water, by confining it in an atmosphere of inert gases is claimed to have the following advantages over wet-quenched coke: Freedom from moisture, which gives a higher net heating value; more uniform size; lower quantity of fines and breeze; stronger, thus avoiding breakage

under loads in the blast furnace with a consequent more even distribution of the blast; reduction in labor cost of manufacture.

The Sulzer system of dry quenching (W. O. Renkin, *Trans.* A.S.M.E., FSP–53–7, 1931) uses the heat in the coke to generate steam. The glowing coke at approximately 1800° F. is charged into a sealed cooling chamber. A fan draws the inert gas through the coke, where it absorbs heat, and then through a boiler, and discharges it into the cooling chamber to repeat the cycle. The air entrapped in the coke burns a small portion of it, the loss amounting to about 0.04%. When the coke has cooled to about 700° F. it is discharged from the cooling chamber. Fresh coke is charged as each lot of quenched coke is withdrawn and the process is continuous.

The heat available for steam generation is given by the formula $H = Tc_1 - tc_2$, where H = heat given up by coke in cooling B.t.u. per lb.; T and t = respectively, charging and withdrawal temperatures of the coke, deg. F.; c_1 and c_2 = mean specific heats of coke at temperatures T and t, respectively. Values of c are given by Terres and Schaller as follows:

Temp., deg. F.	70–482	70–492	70–943	70–1128	70–1306	70–1492	70–1674	70–1848	70–2025
c	0.230	0.267	0.292	0.315	0.331	0.345	0.354	0.361	0.369

Thus the heat available per pound of coke cooled from 1800 to 700° F. will be

$$H = (1800 \times 0.361) - (700 \times 0.292) = 445.4 \text{ B.t.u.}$$

Table 36 gives a comparison of the analyses of wet- and dry-quenched coke.

Table 36.—Analyses of Wet- and Dry-quenched Coke

Analysis	Original Coal	Wet-quenched Coke		Dry-quenched Coke	
		Moisture Free	As Received	Moisture Free	As Received

5. WOOD

HEATING VALUE OF WOOD.—The specific gravity of wood ranges from 0.3 to 1.2; the heating value of dry wood is approximately proportional to the specific gravity, excepting that the presence of resin increases heating value. Newly-felled wood contains moisture, the amount depending on the species, and averaging 40%. Ordinary air-dry wood contains about 25% moisture. Table 37 shows the amount of moisture expelled from wood at gradually increasing temperatures. Table 38 gives the heating values, and Table 39 the analyses of the more common varieties of woods. The heating value as computed by Dulong's formula (see p. 4-03) usually gives lower values than calorimetric determinations. Taking average composition (Table 39), heating value of the dry wood is

$$(14{,}600 \times 0.4956) + 62{,}000\,(0.0611 - 0.4383/8) = 7645 \text{ B.t.u. per lb.}$$

If the wood contains 25% moisture, the net heating value is (0.75 × 7645) minus the heat required to convert the moisture at atmospheric temperature, say 62° F., to steam at atmospheric pressure and to superheat the steam to the temperature of the chimney gases, say 450°. Net heating value based on Dulong's formula then is

$$(0.75 \times 7645) - \{0.25 \times (212-62) + (0.25 \times 970.2) + 0.25(1204.1-970.2)\} = 5398 \text{ B.t.u.}$$

The average heating value as determined by calorimeter is 8671 B.t.u. per lb.

Table 37.—Proportion of Water Expelled from Wood at Various Temperatures

WOOD REFUSE consisting of sawdust, shavings, trimmings, etc., can be efficiently utilized as boiler fuel, providing that the furnace is properly designed. The requirements are ample combustion space, ranging from 5 to 8 cu. ft. per rated boiler horsepower, ample draft, with preferably automatic control, variation in rate of feeding refuse in accordance with the load, and in rate of air supply. Proper instruments, as draft gages, steam flow meter, thermometers and CO_2 indicator assist the firemen to maintain proper operating conditions. Wood refuse commonly is burned at low efficiency, and the balance of the steam requirements are made up by firing coal. Since 2 lb. of wood is roughly equivalent to 1 lb. of coal, any improvement in efficiency of wood burning decreases the cost of coal. E. Winholt (*Trans.* A.S.M.E.,WDI–50–16 A, 1928) cites a case of burning coal and shavings where less than 2 lb. of steam were produced per 1 lb. of shavings. When the shavings were burned alone in a properly designed furnace, approximately 5 lb. of steam were produced per 1 lb. of shavings. For a complete discussion of wood refuse furnaces, see papers by H. W. Beecher, A. C. Sullivan, and C. L. Young, *Mech. Engg.*, July, 1925; E. Winholt, B. A. Parks, *Trans.* A.S.M.E.,WDI–50–16 A and B, 1928; C. S. Gladden, *Trans.* A.S.M.E., FSP–53–3, 1931.

The use of preheated air with wood fuel increases both boiler capacity and efficiency. H. S. Colby (*Trans.* A.S.M.E., FSP–53–3, 1931) gives results of boiler tests in which the use of air preheated to 456° F. increased the capacity of the boiler from 5.66 lb. of water evaporated per sq. ft. of heating surface per hr. to 6.53 lb., and increased the boiler efficiency from 60.4% to 73%.

Wood refuse comprising about 50% each of chip and sawdust, with about 35% moisture, have been used as gas producer fuel (C. E. Snypp, Louisiana Engg. Soc., May 13, 1912). Cypress refuse, with a heating value of 5540 B.t.u. per lb., gave gas of heating value of 130–135 B.t.u. per cu. ft. Pine refuse, of 7605 B.t.u. per lb., gave gas of heating value of 161 B.t.u. per cu. ft.

A Cord of Wood is a pile 4 × 4 × 8 ft. = 128 cu. ft., comprising about 56% solid wood and 44% interstitial spaces. B. E. Fernow (J.C.I.W., vol. iii) gives the percentage of solid wood in various cords as follows: Timber cords, 74.07%; firewood cords (over 6 in. diam.), 69.44%; billet cords (over 3 in. diam.), 55.55%; brush wood cords (less than 3 in. diam.), 18.52%; roots, 37%.

6. CHARCOAL

THE COMPOSITION OF CHARCOAL depends on the maximum temperature during its production and the duration of that temperature. Black alder charcoal showed the following analyses (M. Violette):

	C	H	O	and loss	Ash
Carbonized at 592° F..........	73.24	4.25	21.96	0.55	24.61
" " 1873° F..........	81.97	2.30	14.15	1.58	15.30

Charcoal also is a by-product of the destructive distillation of wood in retorts at temperatures of from 390 to 625° F. Complete carbonization is not obtained. The yield of 1 cord of wood weighing 4000 lb. by this process (J. S. S. Brame, Fuel, p. 20) is: Charcoal 950 lb.; turpentine, 40 gal.; light oils, 16 gal.; heavy oils, 128 gal., together with large

volumes of gases. A typical analysis of these is: Heavy hydrocarbons, 8.16%; CH_4, 12.32%; CO_2, 31.45%; CO, 35.08%; H, 10.94%; N, 2.05%.

THE HEATING VALUE OF CHARCOAL depends on the percentage of carbon and ash, and ranges from 11,000 to 14,000 B.t.u. per lb. It may be calculated by Dulong's formula.

ABSORPTION OF GASES AND WATER BY CHARCOAL.—Freshly burned charcoal contains practically no water, but will absorb 4 to 8% by weight in 24 hr., and 10 to 15% in a few weeks. The absorption of gases by charcoal is (Saussure):

NH_3....	90.00 volumes	N_2O....	40.00 volumes	N............	6.50 volumes
HCl.....	85.00 "	CO_2....	35.00 "	H (carbureted)..	5.00 "
SO_2.....	65.00 "	CO.....	9.42 "	H............	1.75 "
H_2S.....	55.00 "	O.......	9.25 "		

7. MISCELLANEOUS SOLID FUELS

PEAT, air-dried, contains from 15 to 30% of water. A typical analysis is: C, 58%; H, 6%; O, 31%; ash, 5%. Carbon may range from 63 to 51%, and ash from 11to 2%. The specific gravity is about 0.4 but it may be compressed to much greater density. Peat may be burned in the air-dried condition, or it may be briquetted, powdered or coked. The method of preparation, except coking, has little effect on heating value. Poole gives the following values per pound of moisture-free peat from Black Lake, N. Y.: Raw peat, 8237 B.t.u.; machine peat, 8050 B.t.u.; dry powder, 7971 B.t.u.; briquets, steam-dried, 8203 B.t.u. Peat coke ranges from 12,000 to 14,000 B.t.u. per lb. Table 40 gives analyses and maximum and minimum heating values of peats from various states of the U. S. Bulletin 37, Canadian Dept. of Mines gives the results of boiler tests fired with peat as follows: Calorific value of peat, 12,000 to 14,000 B.t.u. per lb.; moisture content, 15 to 20%; calorific value of dry peat, 8070 to 7590 B.t.u. per lb.; evaporation, 4.70 to 4.96 lb. per lb. of dry peat; efficiency, 51.3% to 54.8%.

Table 40.—Analyses and Calorific Values of Moisture-free Peat

SAWDUST AND HOG FUEL.—Hog fuel is the refuse from sawmills which has been reduced to chips of uniform size by a machine called a hog. The unit of hog fuel is 200 cu. ft., equivalent to 1 cord of wood. Variation in voids, moisture and weight of wood will cause the weight of a unit to range from 2500 to 5000 lb., with 4000 lb. as a fair average. Sawdust and hog fuel have the same heating value as the wood from which they are made. (See p. 4–42.)

The evaporative value of hog fuel ranges from 8000 to 13,500 lb. of water evaporated from and at 212° F. per 200 cu. ft. of fuel. A few tests where the fuel has been weighed and the moisture determined have shown evaporations of from 3 to 6 lb. from and at 212° F. per lb. of dry fuel. See papers by H. W. Beecher, C. L. Young and C. C. Simeral, *Mech. Engg.*, July, 1928, for furnace designs and performances with hog fuel. See also p. 4–42.

Sawdust briquets, of a composition of sawdust, 65%, coal dust, 25%, binder, 10% are described in Bulletin 753, U. S. Dept. of Agriculture.

WET TAN BARK, or oak bark, after use in tanning may be burned as fuel in a furnace with very large combustion space. Spent tan contains about 65% moisture, and has an available heating value of about 2665 B.t.u. per lb. (D. M. Myers, *Trans.* A.S.M.E., 1909). The heating value of dry tan was found by six calorimeter tests to be 9504 B.t.u. per lb.; its composition was: C, 51.80%; H, 6.04%; O, 40.74%; ash, 1.42%. Mr. Myers states that with spent tan from 1.5 to 2.08 Hp. may be developed in horizontal tubular boilers per pound of tan.

STRAW from wheat dried at 230° F., and of composition C, 46.1%; H, 5.6%; N, 0.42%; O, 43.7%; ash, 4.1%, had a heating value of 6290 B.t.u. per lb.; with 6% water,

5770 B.t.u.; 10% water, 5448 B.t.u. Dry buckwheat straw showed a heating value of 5590 B.t.u. per lb., and dry flax straw, 6750 B.t.u. Barley straw, of composition C, 36%; H, 5%; N, 0.50%; O, 38%; ash, 4.75%, had a heating value, after deduction of heat lost in evaporating the water, of 5155 B.t.u. per lb.

BAGASSE, or refuse sugar cane after the juice has been extracted, contains 30–50% wood fiber, 0–10% sucrose and 40–60% water. The heating value of dry bagasse is about 8300 B.t.u. per lb. The net heating value is {(1 − moisture content) × heating value of dry bagasse} − (heat required to evaporate the moisture into steam). See Wood, p. 4–41. E. C. Freeland (*Trans.* A.S.M.E., xxxix, p. 611, 1913) gives calorific values of Louisiana bagasse as follows:

Moisture	Gross Calorific Value	Net Calorific Value
56.7%	3620 B.t.u. per lb.	2200 B.t.u. per lb.
48.2%	4800 B.t.u. per lb.	3350 B.t.u. per lb.

According to H. S. Colby (*Trans.* A.S.M.E., FSP-53-3, 1931), the use of air preheated to 400° F. in burning bagasse with 40 to 50% moisture reduced the amount of auxiliary fuel oil from 7 to 2 1/3 gal. per ton of cane crushed, and increased the boiler capacity from 85 to 135% of rating. The relative properties of Louisiana and Cuban bagasse are given by Mr. Freeland in Table 41.

The yield of bagasse from Louisiana cane is 400–600 lb. per ton. The evaporation from and at 212° F. per pound of bagasse is from 2 to 3 1/2 lb.; 4–6 lb. of bagasse are equivalent to 1 lb. of coal (14,000 B.t.u. per lb.); 43–65 lb. are equivalent to 1 gal. of fuel oil (19,000 B.t.u. per lb.). The bagasse from 1 ton of cane will generate 1.16 to 1.44 boiler Hp. per 24 hr. (E. W. Kerr). Drying the bagasse before firing will effect considerable economy. See Bulletin 128, Louisiana Agricultural Expt. Station for designs of driers and of boiler furnaces for bagasse; also *Trans.* A.S.M.E., FSP–53–3, 1931.

Table 41.—Comparison of Heating Values of Cuban and Louisiana Bagasse

Variety of Bagasse	Extraction, percent	Moisture, percent	Fiber, percent	Heating Value, B.t.u. per lb. Total	Net
With 80% Juice Extraction on Weight of Cane					
Cuban	80	32.8	60	5628	4092
Louisiana	80	42.8	50	4816	3345
With Nearly Equal Moisture Contents					
Cuban	75	42.6	48	4807	3335
Louisiana	80	42.8	50	4816	3345

PRESSED FUEL.—Coal briquets comprise fine or slack coal or lignite, mixed with a binder and pressed into small blocks. The most generally used binder is coal tar pitch; other binders that have been used are rosin, asphalt and lime. The binder varies with the coal. A binder that is successful with one coal will be unsatisfactory with another. Briquetting may render fit for use coal that otherwise is valueless, particularly low grade fuel as lignite. Table 42 (U. S. Bureau of Mines, *Bull.* 58, 1912) shows the increase in heating value of lignite due to the removal of moisture in briquetting.

Table 42.—Heating Value of Lignite Briquets

Lignite from	Moisture, percent: In Lignite	In Briquets	Removed	Heating Value, B.t.u. per lb.: Of Lignite	Of Briquets	Increase, percent
Texas	33.0	9.0	24.0	6840	9336	36.5
No. Dakota	40.0	12.0	28.0	6241	9354	50.0
"	42.0	10.0	32.0	6079	9355	54.0
California	40.0	10.0	30.0	6080	9264	52.4

The advantages of briquets, properly made with a suitable binder, as compared with raw fuel, are given in Bull. 58, U. S. Bureau of Mines as: More even and thorough combustion; produce little or no smoke, particularly with smaller sizes; retain their shape in the fire; do not cake and shut off air from upper surface of fire; burn to a fine ash without clinkering; fire requires less care; evaporative power greater than that of raw fuel at all rates of evaporation; weather resisting properties greater than that of raw fuel; higher rates of combustion are possible than with run-of-mine coal; loss from breakage during transportation is less; no danger of spontaneous combustion; block shaped briquets require less storage space than run-of-mine coal; have higher calorific value than the raw fuel. Briquets may be used as a substitute for raw fuel in domestic stoves and heaters and in locomotives. They usually cannot compete with coal in power boilers.

OIL REFINING WASTES may be burned as fuel in special types of burners. These wastes comprise petroleum coke, burned in pulverized form, refinery acid sludge, soda bottoms, neutralized sludge, acid tar, wax tailings and flux bottoms. The heating value of sludge ranges from 17,500 to 8000 B.t.u. per lb. A combined type of burner is used which is capable of burning either gaseous, liquid or pulverized solid fuel without changing any part of the burner. Several such types of burners have been devised, some of which will burn all three types of fuel simultaneously. In one of these, gaseous fuel enters the furnace from a ring-shaped gas chamber, through an annular opening, and meets a rapidly rotating current of air entering the burner through an air register in the outer end. Pulverized solid fuel and air enter tangentially a rifled coal-burner body, coaxial with and adjacent to the gas chamber. The stream of fuel is mixed with and carried by the secondary air from the register, rotating in the same direction. The oil is sprayed from a mechanical atomizer tip, located at the outer end of the coal-burner body. The oil issues in a divergent conical sheet, through which all of the secondary combustion air from the register passes. See paper by R. C. Vroom (*Trans.* A.S.M.E., FSP-53-27, 1931) for description of several types of combined burners, and discussion on burning of refinery waste. Refinery waste is used as fuel in the plant of the Louisiana Steam Products, Baton Rouge, La., together with natural gas and fuel oil, generating about 350,000 lb. of steam per hour. See article by J. F. Muir, *Power*, Jan. 13, 1931, and paper by H. J. Klotz, *Trans.* A.S.M.E., FSP-54-6, 1932.

LIQUID FUELS

By Harry F. Tapp

1. CHARACTERISTICS OF FUEL OIL

FUEL OIL is defined (A.S.T.M., D288-31 T) as any liquid or liquefiable petroleum product burned for the generation of heat in an industrial or household furnace or firebox, or for the generation of power in a Diesel engine, exclusive of oils with a flash point below 100° F., Tag closed tester, and oils burned in cotton or wool-wick burners. Fuel oils are classed as: 1. Residual oils, *i.e.*, topped crude petroleums or viscous residuums obtained in refinery operations. 2. Distillate oils, derived directly or indirectly from crude petroleum. 3. Crude petroleums and weathered crude petroleums of relatively low commercial value. 4. Blended fuels, *i.e.*, mixtures of two or more of the above classes.

COMMERCIAL STANDARD SPECIFICATIONS for fuel oils cover six grades. They are limited by detailed requirements summarized in Table 1. The several grades are defined as: No. 1.—A light domestic fuel oil; a distillate fuel oil for burners requiring a volatile fuel. No. 2.—Medium domestic fuel oil; a distillate fuel oil for burners requiring a moderately volatile fuel. No. 3.—Heavy domestic fuel oil; a distillate fuel oil for burners requiring low viscosity. No. 4.—Industrial fuel oil, for oil burners requiring low viscosity fuel oil. No. 5.—Medium industrial oil, for burners adapted to medium viscosity fuel oil. No. 6.—Heavy industrial fuel oil, for burners equipped with oil preheaters, permitting use of high viscosity oil.

Flash Point (A.S.T.M., D93-22) is the temperature to which oil must be heated to give off sufficient vapor to form an inflammable mixture with air. It varies with apparatus and procedure used, and both must be specified when flash point is stated. The minimum flash point usually is controlled by law. If no legal requirements exist, minimum values of Table 1 are used. Maximum values are specified for oils 1-3 to insure required ease of ignition.

Water and Sediment (A.S.T.M., D96-28) are excluded almost entirely in oils 1-3, but allowed to limited extent in oils 4-6. Water and sediment are determined together by the centrifuge, except that in oil No. 6, water is determined by distillation and sediment by extraction with benzol.

Table 1.—Commercial Standard Specifications for Fuel Oil
(A.S.T.M. Designation D396–34T.)

Pour Point (A.S.T.M., D97–28) is the lowest temperature at which oil will flow under prescribed conditions.

Laboratory Distillation (A.S.T.M., D86–27 for oil 1, A.S.T.M., D158–28 for oils 2 and 3) of a sample under prescribed conditions is an index of volatility. The 10% and 90% points represent, respectively, temperatures at which 10% and 90% of the sample are distilled over. The end point is the maximum temperature recorded by the distillation thermometer at the end of distillation. The 10% point is an index of ease of ignition. The 90% point and the end point are specified to insure that the oil will burn completely and produce a minimum of carbon.

Viscosity * (A.S.T.M., D88–26) is the time in seconds in which a definite volume of oil will pass through a tube of specified dimensions at a definite temperature. It is a measure of the resistance of oil to flow. Viscosity decreases as temperature increases; preheating makes possible the use of oils of relatively high viscosities at normal temperatures. Maximum viscosity is limited because of its effect on oil flow in pipe lines, and on the degree of atomization that can be had in given equipment. The Saybolt Universal viscosimeter is used for low-viscosity fuel oils, and the Saybolt Furol viscosimeter for heavier oils. Other types of viscosimeters used with fuel oils are the Engler and Redwood.

The Nat. Elect. Light Assoc. Prime Movers Committee, 1931, gives a curve of the temperature-viscosity relations of a California fuel oil, from which the following figures are taken. Viscosity is in Saybolt universal seconds.

Temp. Deg. F.....	90	100	110	120	130	140	150	170	190	210
Viscosity.........	2300	1600	1150	820	600	450	340	200	110	85

Table 2, from Day's Handbook of the Petroleum Industry, gives approximate factors for converting viscosity as determined by one instrument to viscosity as determined by another. For additional information on viscosity determination and viscosimeters, see Battle's Industrial Oil Engineering (Lippincott) and Day's Handbook of the Petroleum Industry (John Wiley and Sons).

The viscosity-temperature chart (A.S.T.M. Method D341–32T) is convenient for estimating viscosities and temperatures other than standard test temperatures.

Specific Gravity is the ratio between the weight of any volume of oil at 60° F. and the weight of an equal volume of pure water at 60° F. It always is used for solid petroleum products and often for liquids. Except for exact laboratory work, gravity determinations on liquid petroleum are made by hydrometer (A.S.T.M., D287–30T), the depth to which it sinks in the liquid, as shown by the scale, determining specific gravity direct, or the gravity in degrees A.P.I. The A.P.I. gravity of pure water at 60° F. is 10°. The range for fuel oils is approximately 10° to 40° A.P.I.

To overcome the confusion due to the use of two so-called Baumé scales, for light liquids, the American Petroleum Institute, the U. S. Bureau of Mines and the U. S. Bureau of Standards agreed, in 1921, to recommend that only the scale based on the modulus 141.5 be used in the petroleum-oil industry, and that it be known as the A.P.I. scale. The relation of degrees A.P.I. to specific gravity is expressed by

$$\text{Degrees A.P.I.} = \{141.5/(\text{Sp. gr. } 60°/60° \text{ F.})\} - 131.5$$

Liquid fuels are purchased by volume. All gravity readings and volume determina-

* Absolute viscosity is the force required to move a plane surface of 1 sq. cm. at a speed of 1 cm. per sec. with reference to another plane surface, separated from the first by a layer of liquid 1 cm. thick. See p. 4–56.

* Engler degrees are obtained by dividing the outflow time in seconds for 200 cc. of the oil, by the outflow time in seconds for 200 cc. of water at 68° F. The later figure is the "water factor" and should be between 51 and 52 seconds.

tions should be corrected to the standard temperature, 60° F. For correction tables, see Circular 154, U. S. Bureau of Standards. The unit of volume is the barrel (42 U. S. gal.) = 5.6 cu. ft. approx. Weight of fuel oil ordinarily is taken as 60 lb. per cu. ft., whence 1 bbl. = 336 lb. at 60° F. The coefficient of expansion of the average fuel oil is approximately 0.0004 per deg. F.

Carbon Residue. (A.S.T.M., D189-30.)—The carbon residue test, in connection with other tests and the use for which the oil is intended, furnishes information and throws light on the relative carbon-forming qualities of an oil. For medium viscosity and blended oils it is used to detect heavy residual products.

Ash. (A.S.T.M. D128-27.)—The ash test determines the amount of non-combustible impurities, which come principally from the natural salts present in the crude oil, or from chemicals used in refinery operations. They also may come from scale and dirt picked up from containers and pipes. Ash in fuel oils causes rapid deterioration of refractory materials in the combustion chamber, particularly at high temperatures. Some ash-producing impurities are abrasive and destructive to pumps, valves, control equipment and other burner parts. Ash specifications are included to minimize these operating difficulties.

Specific Heat of fuel oils varies from 0.4 to 0.55 for the temperature range generally used. Specific heat increases with temperature, and decreases as the specific gravity of the oil increases. The Prime-movers Committee of the Natl. Elect. Light Assoc., 1930, gives the following mean specific heats of a California oil of 18° A.P.I.

Temp. deg. F......	100	120	140	160	180	200	220	240	260	280
Mean Specific Heat.	0.450	.456	.463	.470	.479	.490	.502	.514	.527	541

HEAT CONTENT.—Exact determination of the heat content of fuel oil is made in a bomb calorimeter. Calorimeter determination is unnecessary unless the oil is bought on a B.t.u. basis. The heat content so varies with the gravity that the latter is a reliable index of the former. Approximate heating values for heavy oils may be computed by: B.t.u. per lb. = 18,650 + 40 (A.P.I.° − 10). See Publication 97, U. S. Bureau of Standards, for additional information on heat content. See Table 3 for analysis and heat content of typical oils.

CHEMICAL COMPOSITION OF PETROLEUM.—Petroleum is composed of carbon and hydrogen combined as hydrocarbons, and small quantities of oxygen, nitrogen, and sulphur. The range of ultimate analysis of fuel oils is C, 80-87%, H_2, 10-17%, S, 0-6%, O_2 and N_2, 0-6%.

The ultimate analysis determines the theoretical air required for combustion (See *Air Required to Burn Various Fuels*, p. 4-07), and the maximum CO_2 possible, which depends on the chemical analysis, or on the carbon-hydrogen ratio. The carbon-hydrogen ratio is

$(C + 0.4\,S)/H$. Table 4 gives relation between C–H ratio, percent of excess air, and CO_2. In practice, burning of fuel oil will give CO_2 as follows: High average, 12–14%; average, 10–12%; minimum (poor), 8%.

SPECIFIC HEAT OF FLUE GAS with oil fuel varies with temperature. F. G. Philo (*Trans.* A.S.M.E. FSP-54-11, 1932) presents a curve which shows it to vary in a straight line from 0.245 at 300° F. to 0.27 at 2000° F.

OIL COMBUSTION THEORIES.—Three theories of the burning of hydrocarbons are: 1. The hydrogen burns with oxygen before the carbon unites with oxygen. 2. The carbon burns in preference to the hydrogen. 3. A preliminary combination of oxygen with the hydrocarbon forms an intermediate hydroxylated compound, which, in turn, burns or is broken down thermally.

Investigations by W. A. Bone and others indicate a combination of hydrocarbons with oxygen, preliminary to final combustion (theory 3). Hydrocarbons combine with oxygen to form alcohol and aldehydes as a preliminary to burning to CO, CO_2, and H_2O. This holds true at all temperatures. Intermediate reactions at high temperatures may vary, but the initial hydroxylated molecule always is formed at the first contact with oxygen. No selective combustion of either carbon or the hydrogen of the hydrocarbon is evident. The initial addition of oxygen to the hydrocarbon molecule forms an alcohol which reacts with more oxygen to form an aldehyde. The aldehyde frequently breaks down into intermediate combustible gases, CO and H_2, or the aldehyde may burn completely to CO_2 and H_2O. This process is termed *hydroxylation.*

The heavier hydrocarbons usually undergo reactions other than simple hydroxylation, as do the lighter hydrocarbons if conditions are unfavorable to forming hydroxylated compounds. Heavy hydrocarbons may be cracked to saturated and unsaturated lighter hydrocarbons, or they may be decomposed completely into carbon and hydrogen. The lightest saturated hydrocarbons are cracked much more slowly than the heavier hydrocarbons.

In ordinary combustion of hydrocarbons no soot will form if conditions favor hydroxylation, *viz.*, premixture with air and ample time for oxygen to enter into the hydrocarbon molecule. If conditions favor cracking, a smoky flame results. For example, if hydrocarbons and oxygen from the air are not thoroughly mixed, the heat due to burning part of the hydrocarbons decomposes or cracks the remainder. For the conditions of ordinary combustion, the hydrocarbon, plus a small amount of oxygen, may be assumed to become a mixture of $CO + H_2$, which mixture burns as if the reactions were $2H_2 + O_2 = 2H_2O$, and $2CO + O_2 = 2CO_2$.

Soot and Scale Deposits from Oil Fuel.—The soot deposited by heavy oil fuel may contain acid-forming material, principally from the sulphur in the oil. If it becomes wet from boiler leakage or other sources, serious corrosion may result. To avoid this, the soot should be blown out at least every 48 hr. Representative soot and scale deposits (Report of Prime-movers Committee, Natl. Elect. Light Assoc., 1930) analyzed as follows:

Soot.—Loss on ignition (carbon, etc.), 51.15%; SiO_2, 1.89%; Fe_2O_3, 12.50%; CaO,

0.60%; MgO, 0.20%; alkalis as Na_2O, 6.24%; Cl, trace; sulphates, as SO_3, 27.4%. The acidity of this soot calculated as H_2SO_4, is 21.13%.

Scale.—Insolubles, as SiO_2, etc., 4.2%; Fe_2O_3, 1.9%; NiO, 2.0%; $CaSO_4$, 2.7%; Na_2SO_4, 89.2%. Some of the sodium sulphate was present as the acid sulphate.

COMPARATIVE FUEL COSTS are estimates of performance based on known and assumed factors, supposed to represent average conditions. Known factors are cost per unit, and heat content per unit. The assumed factor is the efficiency of utilization of the heat content of the fuel. To compare fuel costs intelligently, conditions under which the fuels are used must be studied, and each problem considered separately. The accuracy of an estimate of the probable relative consumption of two fuels will be in direct proportion to the accuracy of information available.

A formula for estimating the relative value of oil and other fuels is

$$X_o = (W_c \times H_c \times E_c) \div (H_o \times E_o)$$

where X_0 = units of fuel oil per unit of competing fuel; W_c = unit of weight or volume of competing fuel; H_c = heat content per unit of weight or volume of competing fuel; E_c = efficiency at which competing fuel is utilized; H_0 = heat content per unit of weight or volume of fuel oil; E_0 = efficiency at which fuel oil is utilized. Unit cost figures of the two fuels then may be used to determine comparative costs.

The actual efficiency of a given heating operation can be determined only by test. If tests are not available, assumed efficiencies must be used, based on knowledge and experience. Factors to be considered are fuel used, air-fuel ratio, furnace volume, combustion temperatures, amount and condition of heating surface, relation between heating surface and flow of gases, the heat absorbing medium (water, air, metal, etc.), load factor, load fluctuation, and temperature of the escaping combustion gases.

Other factors than fuel cost that must be considered to determine real comparative operating cost, are: 1. Cost of installation. 2. Labor. 3. Results obtained, *i.e.*, quality of finished product. 4. Uniformity or flexibility of heat control. 5. Reliability. 6. Maintenance. 7. Depreciation of equipment. 8. Operating cost of power for equipment, including auxiliaries. Installation cost is important, but should not be considered until study of the whole problem is complete. The advantages of a given fuel may so outweigh this factor as to make it negligible in the final analysis.

ADVANTAGES OF FUEL OIL.—(Haslam and Russell, Fuels and Their Combustion.) 1. Weight 30% less and space occupied 50% less than coal of equivalent heat content. 2. No deterioration in storage. 3. Freedom from spontaneous combustion. 4. Storage may be distant from furnaces. 5. Fuel is immediately available and may be stored or removed with practically no labor. 6. High combustion rates per cubic foot of combustion space. 7. Great flexibility in furnaces to readily and economically carry peak and valley loads. 8. Low labor cost to handle oil at the furnace and to clean boiler tubes 9. No labor for cleaning fires or removing ashes. 10. High efficiency and practically no smoke. 11. Absence of wear on machinery due to ash and dust. 12. Low pressure drop through the furnace. 13. A minimum of excess air required for complete combustion.

2. METHODS OF BURNING FUEL OIL

OIL BURNER TYPES.—Oil burners can be classified as: 1. Natural draft vaporizing burner. 2. Natural draft atomizing burner. 3. Mechanical draft vaporizing burner 4. Mechancal draft atomizing burner. They also can be classified, according to most common use made of each class, as: A. Domestic burners, using oils Nos. 1, 2 and 3, full- or semi-automatic, or manually controlled, used in domestic heating systems. B. Commercial burners, using oils Nos. 3, 4, 5 or 6, full- or semi-automatic, or manually controlled. used in heating boilers for apartment houses, office, manufacturing, and public buildings, etc., usually semi-automatic. C. Industrial burners using oil No. 6, used for industrial or power steam generation, and for using any grade of oil from No. 1 to 6, to supply heat for industrial processes.

Mechanical Draft Burners use a fan or blower to supply the air for combustion. Mechanical draft may be used with either vaporizing or atomizing burners. Its advantages are: 1. A more constant supply of air under varying draft conditions. 2. Velocity of the air may be used to increase turbulence or mixing effect. 3. Sufficient air for clean combustion from a cold starting condition is supplied without depending on chimney draft. 4. Can be used to develop high ratings when necessary. Its disadvantages are: 1. Increased first cost. 2. Cost of power. 3. Mechanical wear and noise.

ATOMIZATION breaks the fuel into fine particles that readily mix with the air for combustion. It then burns with a clean hot flame, being vaporized and oxidized by the resulting combustion before cracking takes place. In pressure atomizing burners the

fineness of spray increases as pressure increases and as viscosity decreases. In burning No. 6 oil, a pulsating flame results if viscosity is reduced to a point where the fuel tends to vaporize. Table 5, from U. S. Navy Manual of Engineering Instruction, shows the effect of pressure and viscosity on spray angles. This effect will vary with different burners and must be determined for each design size. If particles of oil or vaporized oil escape from the combustion zone because of improper atomization, combustion chamber design or air control, their heat content will escape with the flue gases. These losses are known as hydrocarbon losses and may be determined with the Burrell-Orsat gas analysis apparatus. Factors affecting hydrocarbon losses are: 1. Insufficient turbulence. 2. Cracking of oil and vapor in hot inert gases of combustion. 3. Cooling effect of excess air.

The advantages of atomization of oil are: 1. Atomizing burners can be used with heavier grades of oil. 2. Can be adapted to large applications because of larger capacity range. 3. Complete combustion is assured by the ability of the small particles to penetrate turbulent combustion. 4. Accurate metering of the fuel is possible, resulting in uniform combustion conditions. Disadvantages are: 1. Necessity of power-driven units to effect atomization. 2. Higher installation cost.

Table 5.—Effect of Pressure and Viscosity on Spray Angle of Pressure Atomizing Burners

Size	88° F. = 340 Seconds Saybolt Universal Viscosity					125° F. = 150 Seconds Saybolt Universal Viscosity					200° F. = 50 Seconds Saybolt Universal Viscosity

Mechanical Pressure Atomizers are designed for capacities ranging from 9 to 3000 lb. of oil per hour per burner. Oil is delivered to the burner, preheated if necessary for pumping and atomization, under pressures ranging from 40 to 250 lb. per sq. in. or more, depending on the quantity and grade of oil used. Pressure is varied to increase or decrease the capacity of the tip. With low-capacity burners, 1.35 to 10 gal. per hr. (diameter less than 0.030 in.), the capacity range generally is determined at pressures of 40 to 150 lb. per sq. in. for the lighter oils Nos. 1 to 4; for the heavier more viscous grades Nos. 5 and 6, the orifice size is increased and the capacities determined at pressures of 100 to 250 lb. per sq. in. The oil leaving the atomizer tip is broken into fine spray by centrifugal force, and by the rapid expansion following a sudden reduction in pressure. A regulating valve, manual or automatic, maintains a uniform pressure at the atomizer. Automatic valves usually are controlled by steam pressure.

Because of the high pressures used, the dimensions of the various parts of the atomizer must be held to limits of 0.001 to 0.005 in., if uniform results are to be expected. Even slight imperfections in the oil passages and orifice will cause faulty atomization. Care must be used in handling and cleaning burner tips. In shipping, storing and handling, they should be individually wrapped and protected against damage. The nose of the atomizer should have a shallow counterbore to protect the orifice.

The principal advantages of mechanical pressure atomization are: 1. Simplicity. 2. Uniform atomization. 3. Accurate and uniform metering of fuel. 4. High efficiency at high ratings. The disadvantages are: 1. Clogging of small orifices and passages (can be reduced materially by providing suitable strainers). 2. Capacity of individual tips is limited to narrow range (the larger the tip the greater the capacity range). 3. High preheating temperature required with heavy grades of oil.

Steam-atomizing Burners are classified as outside mixers or inside mixers. Both types can be designed to produce either round or flat flames. They are designed for capacities ranging from 5 to 1500 lb. of oil per hour per burner. A burner using steam for atomizing also may be used with compressed air. The oil is delivered to the burner oil-regulating valve at pressures ranging from 5 to 50 lb. per sq. in., preheated if necessary for pumping and atomization. The preheating temperature for steam-atomizing burners usually is lower than that required for mechanical pressure atomizers, as the viscosity is decreased by the heat of the steam used for atomization.

Steam usually is delivered to the burner steam-regulating valve at boiler pressure. It should be dry or superheated, as moisture causes the flame to sputter. The amount of steam used for atomization varies with the design of the burner, the skill of the operator,

and the boiler capacity. Under average conditions it ranges from 2 to 4% of boiler output. With competent operators and well-designed burners, the steam consumed may be as low as 1 1/2 to 2%; with careless operators or poor burner design it may be 4 to 6% or more. See Fig. 1 from paper by E. H. Peabody, The Burning of Liquid Fuel (*Trans.* A.S.M.E. FSP-50-13, 1928).

The principal advantages of steam-atomizing burners are: 1. Simplicity of design. 2. Low first cost of installation. 3. Low preheating temperature required. 4. Low pumping pressures. 5. Flexibility and high efficiencies at low and moderate rates of driving. 6. Ability to burn extremely heavy oils. The disadvantages are: 1. Steam consumption of burners. 2. Limitation in boiler capacity. 3. Decreased efficiency at high rates of driving.

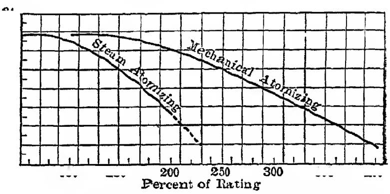

Fig. 1. Comparison of Steam and Mechanical Atomizing Burners

Low-pressure Air Atomizers.—Atomization of light oils can be accomplished satisfactorily with low-pressure air, without depending on oil pressure, if a sufficient quantity of air is supplied. The energy in a large volume of low-pressure air equals the energy in smaller volumes of air at higher pressures. The quantity of air required depends on design of burner, degree of atomization required, grade of oil, its pressure and temperature. Table 6 gives the approximate minimum quantity of atomizing air required at different pressures.

Table 6.—Percent of Combustion Air Required for Atomization

Air pressure, lb. per sq. in.	0.25	0.50		2	5	10	25	60	100
Percent of air required	68	52	42	33	25	19	13	9	7

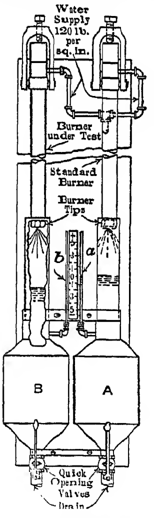

Fig. 2. Testing Device for Mechanical Oil Burner Tips

Mechanical Rotary Atomizers.—Oil is fed by a pump or gravity through a regulating valve to a rapidly rotating tapered cup. The oil enters at the rear, or point of least diameter, is carried forward and spread out in a film on the inner surface, and atomized by centrifugal force as it is thrown off the edge of the cup. The cup is rotated either by a motor or low-pressure air turbine. Rotary cup burners are designed for capacities ranging from 5 to 2000 lb. of oil per hour per burner.

The principal advantages of rotary disc, or cup, burners, are: 1. Flexibility over large capacity ranges. 2. High efficiencies. 3. Ability to burn heavy oils at low preheating temperatures. The disadvantages are: 1. High first cost. 2. Vibration and noise from moving parts. 3. Inefficient combustion resulting from operating burner beyond its rated capacity.

COMBINATION OIL AND GAS BURNERS.—The need for a reliable fuel supply in installations burning natural gas has led to the development of combination oil and gas burners. The necessity of thoroughly mixing natural gas and air for combustion makes the oil burner of any type ideal equipment for such combinations. The oil and gas ratings are such as to permit either fuel to be used for carrying the load.

TESTING OF OIL BURNER TIPS.—To insure equal amounts of oil being fed to each burner in a battery, frequent tests of burner tips are advisable. Tips wear, and leakage between burner parts may occur. Both tend to increase flow, and considerable variation in capacity of individual burners thus may exist. Natl. Elect. Light Assoc. Publication No. 30 illustrates the testing device shown in Fig. 2. The burner under test is compared with a standard burner by admitting water under 120 lb. per sq. in. pressure to both burners simultaneously. The discharge is caught in two receivers A and B fitted with manometers *a* and *b* to show the water level in each. The manometer of the test receiver B is graduated to show its contents in percentage of the standard receiver A. Flow continues through the two burners until the manometer on the standard receiver reads zero, when the inlet valve is closed and the variation of the test burner from standard is read directly on the test receiver manometer. A test of 60 used burners showed a maximum variation from standard of 16%; 40 new burners showed a maximum variation of 7%. All were corrected within 2% of standard.

PREPARATION OF LIQUID FUEL.—Many variations and combinations of the methods used to prepare liquid fuel for combustion, including domestic burners, will be found in Handbook of Oil Burning, by H. F. Tapp, 1931.

For information on various types of oil burners the data published by the following manufacturers is suggested.

Pressure Atomizing Burners.—*a*. Domestic; Automatic Delco Appliance Corp., Rochester, N. Y.; Gilbert and Barker Mfg. Co., Springfield, Mass.; May Oil Burner Corp., Baltimore, Md.

b. Commercial, Industrial and Marine: Anthony Co., Long Island City, N. Y.; The Babcock and Wilcox Co., New York; The Engineer Co., New York; Peabody Engineering Co., New York.

Air and Steam Atomizing Burners.—*a*. Domestic Automatic Air Atomizing: Caloroil Burner Corp., Hartford, Conn.; General Electric Co., Schenectady, N. Y.

b. Commercial and Industrial: W. N. Best Co., New York; National Airoil Burner Co., Philadelphia; Staples and Pfeiffer, Ltd., San Francisco.

Rotary Atomizing Burners.—*a*. Domestic Automatic: Automatic Burner Corp., Chicago; Timken Silent Automatic Co., Detroit; U. S. Burner Corp., Hartford, Conn.

b. Commercial, Industrial and Marine: S. T. Johnson, Oakland, Cal.; Ray Burner Co., San Francisco; Petroleum Heat and Power Co., Stamford, Conn.

Vaporizing Burners.—Domestic Automatic: Franklin Oil Heating, Inc., Columbus, Ohio; McIlvaine Burner Corp., Chicago; Par Appliances, Inc., La Crosse, Wis.

OIL BURNER CONTROLS may be classified as: 1. Manual. 2. Continuous operation (high-low). 3. Continuous operation (graduated control). 4. Intermittent operation (full automatic). 5. Combinations of 2 and 4, or of 3 and 4. With the exception of manual control and operation, the system may respond to changes in temperature or pressure, or both, through electrically or mechanically actuated devices. For data on oil-burner controls the data published by the following manufacturers is suggested.

Electric Controls for domestic, commercial and industrial burners: Minneapolis-Honeywell Co., Minneapolis, Minn.; Mercoid Corp., Chicago; Penn Electric Switch Co., Des Moines, Iowa.

Mechanical Controls for commercial and industrial burners. Fulton-Sylphon Co., Knoxville, Tenn.; Kieley Mueller Inc., New York; Preferred Utilities Mfg. Co., New York; Smoot Engineering Corp., Chicago.

A Full Automatic Control System incorporates a device responsive to changes in temperature or pressure, a sequence control device, and a device to ignite the oil or combustible mixture. If all operations except ignition are performed automatically, the control is *semi-automatic*. The method of control depends on the design characteristic of the burner, grade and amount of oil burned, and character of the load. Manual control largely is used in the industries for metal melting, varnish cooking, forge furnaces, ceramic furnaces, etc., where temperature or pressure control is relatively unimportant or where the operation requires close attention and the temperatures or pressures are changed during critical reactions in the process. In general, however, automatic controls are advantageous in most applications.

Limit Controls to protect boilers or furnaces from excessive operation of the burner respond to the amount of pressure or heat developed in boiler or furnace. These controls usually are designed for electric connection to the control of the burner. They are so connected that if the boiler or furnace control has broken the circuit, due to excess pressure or heat, the burner is inoperative regardless of the demand from the thermostat or other normal control device.

BURNER AND FLAME APPLICATION.—The design and type of burner governs the general shape of the flame, and determines in part the method of installing the burner and the path of flame in the boiler or furnace. Pressure atomizing burners usually have a cone-shaped flame, the included angle varying between 45 and 120 deg., depending on the atomizer tip design and control of air flow. By controlling air flow, it also is possible to obtain a flat flame. Steam- and air-atomizing burners in general can be designed to produce either flat or cone-shaped flames; rotary atomizers are limited to cone-shaped flames, whose included angle may be varied by control of air flow about the atomizer cup. Specific instructions for control of flame shape are given in manufacturers' instructions. Most burners are sufficiently flexible in this respect to be generally adaptable to boiler settings, but the type of boiler or furnace, and also the shape and size of the combustion chamber should be considered in selecting the type and number of burners. No more burners should be used than are needed to utilize the available combustion volume with sufficient flexibility to meet existing load conditions. For example, for a relatively narrow and deep combustion chamber, one burner is preferable, provided the oil rate can be varied to suit both the minimum and maximum load.

Adequate flame distribution requires that the flame conform as nearly as possible to the shape of the combustion chamber, for the reasons: 1. Maximum combustion volume is utilized. 2. Provides for thorough mixing of fuel and air during combustion process, insuring efficient combustion. 3. Permits using a minimum of excess air. 4. Reduces

hydrocarbon losses. 5. Is conducive to quiet combustion. 6. Maximum thickness of flame is obtained, providing maximum transfer of radiant heat. 7. Reduces flame impingement on refractory walls of combustion chamber.

DESIGN OF COMBUSTION CHAMBER.—Refractory combustion chambers are used, principally: 1. To permit maintenance of high temperature in combustion chamber to quickly vaporize raw fuel injected by the burner. 2. To protect parts of boiler or furnace that are not cooled properly. Additional benefit may be obtained by building brickwork to guide and increase flame travel in the combustion chamber.

The more important points to be considered in the design of combustion chambers are: 1. The refractory surfaces provide a radiant heating surface, which aids in combustion of the oil. Hence, it should be of minimum bulk so that it will heat rapidly and bring the combustion chamber to an efficient operating temperature. 2. Usually the combustion chamber must be so designed as to protect metal parts that are not cooled by water. 3. The shape of the combustion chamber should be such as to: *a*, get maximum flame distribution, giving consideration to the size and shape of the flame; *b*, provide maximum flame travel, taking into consideration location of fuel passes to the indirect heating surface. 4. All the direct heating surface of the furnace should, if possible, be exposed to the radiant heat of the flame and should not be covered with refractory material, except to prevent direct flame impingement. 5. For uniformly satisfactory flame distribution, square corners must be avoided; surfaces of the combustion chamber should curve upward to increase the turbulence within the chamber without creating downward eddies from the flame. 6. The center line of the burner should be high enough to prevent flame impingement on the hearth and allow air to circulate below the flame to insure complete combustion.

COMBUSTION VOLUME.—In any installation two combustion volumes are to be considered: 1. Available volume. 2. Effective volume.

Available Combustion Volume is the total volume enclosed by the boiler and its foundation or setting which may be used as combustion space. This is space enclosed by the floor or hearth, side walls, or water legs, up to the crown sheet or equivalent, which is a plane tangent to the bottom of the lowest row of tubes or other water-backed surfaces. A bridge wall should be considered as a side wall.

Effective Combustion Volume is the space actually occupied by the flame and circulating gases. It is controlled by the design, application and adjustment of the burner, and should be as nearly equal to the required available volume as conditions will permit. The required combustion volume varies with different classes of work, and usually is expressed as B.t.u. released per cu. ft. per hr. There are no fixed rules except that, in general, higher temperatures are involved with higher B.t.u. releases, and must be considered in connection with the life and services of refractory materials and structural supports of boiler or furnace. The intensity of combustion noise also tends to increase with high heat releases. Unless the refractory walls of the combustion chamber are cooled, high B.t.u. releases should not be used except in emergencies. The average range of B.t.u. releases for various types of installation is given in Table 7.

Table 7.—Average Range of B.t.u. Releases for Various Classes of Oil-burning Installations

Type of Installation	B.t.u Release per cu. ft. per hr.
Commercial heating boilers (large)	40,000– 70,000
High-pressure steam boilers (medium)...	40,000– 70,000
High-pressure steam boilers (large)	40,000–200,000
High-pressure steam boilers (marine)	40,000–100,000
High-pressure steam boilers (naval).....	60,000–200,000
Industrial furnaces....................	30,000–100,000

FIREBRICK AND REFRACTORY CEMENT.—Firebrick and refractory cement should be selected on the basis of the service in which they are used. A grade higher than absolutely necessary should be chosen because of abuse under extreme operating conditions. The life of refractory material in combustion chambers is shortened by sustained high temperature, rapid changes in temperature, and by panting or vibration from combustion. High temperatures result from: Operation above normal rating; normal operation with insufficient combustion chamber volume; flame impingement; combustion chambers designed for high B.t.u. releases. Rapid temperature changes may be reduced to a minimum by the operating personnel. A cold boiler should be brought up to operating temperature and pressure as slowly as possible. When securing the boiler, registers and dampers must be closed tightly to allow the boiler to cool slowly. Panting usually

is due to improper drafts, faulty atomization, fluctuating oil pressure or high B.t.u. releases. Sputtering results from water in the oil or wet steam supplied to steam-atomizing burners.

FURNACE FLOORS.—The burner manufacturer usually specifies the furnace floor construction. The several layers are as follows: 1. Insulating brick or material. 2. First course of brick, dry, laid $^1/_{16}$ in. apart to provide for expansion, joints broken between adjacent rows. 3. Dry refractory cement, filling all cracks and covering bricks to depth of $^1/_8$ in. 4. Second course of brick similar to first, overlapping joints in first course. 5. Dry refractory cement as in (3). After firing, the bricks take a permanent set and the cement vitrifies to a hard surface. For air ports built into the floor, the bricks may be set in refractory cement mortar.

3. STORAGE OF FUEL OIL

FUEL OIL STORAGE TANKS generally are classified by material, as steel or concrete; by size in gallons, etc.; by location, as exposed or inside, under-ground or buried; by use, as light or heavy oil tanks. The essential requirements for tanks are tightness and durability. The specifications of Underwriters' Laboratories, Chicago, for labeled tanks, or of the National Board of Fire Underwriters, are generally accepted standards. See Tables 8, 9 and 10. Some cities and states require special construction, and local regulations should be studied before installation. Tanks for heavy oil usually have a manhole and provision for a tank preheater, using either steam or hot water. Such tanks should be designed to heat the oil in the vicinity of the suction pipe to not over 100° F. See Table 11.

Table 8.—Specifications for Under-ground Oil Storage Tanks

(National Board of Fire Underwriters, Revised 1931)

Maximum capacity, gal.	285	560	1100	4000	12,000	20,000	30,000
Gage of metal	16	14	12	7	$^1/_4$ in.	$^5/_{16}$ in.	$^3/_8$ in.
Weight of metal, lb. per sq. ft.	2.50	3.125	4.375	7.50	10.00	12.50	15.00

Top of under-ground tanks to be not less than 2 ft. under-ground. Material to be galvanized steel, basic open-hearth, or wrought iron. Joints to be welded, or riveted and caulked.

Table 9.—Specifications for Above-ground Oil Storage Tanks

(National Board of Fire Underwriters, Revised 1931)

Maximum capacity, gal.	60	350	560	1100	Over 1100
Gage of metal	18	16	14	12	See Note 1

NOTE 1. Thickness of metal for above ground tanks to be calculated by the following formula: $t = 2.5\ HDS/TE$, where t = thickness of metal, in.; H = height of tank above bottom of ring under consideration, ft.; D = diam. of tank, ft.; S = specific gravity of liquid; T = tensile strength of plate, lb. per sq. in.; E = efficiency of joint in ring. Minimum values of t are: Tanks not over 6 ft. diam., $t = {}^3/_{16}$ in.; tanks over 6 ft. diam., $t = {}^1/_4$ in.

Table 10.—Spacing of Fuel Oil Tanks

(National Board of Fire Underwriters)

Distance between Tanks, ft.	Maximum Capacity, gal.		Distance between Tanks, ft.	Maximum Capacity, gal.		Distance between Tanks, ft.	Maximum Capacity, gal., Above-ground
	Under-ground	Above-ground		Under-ground	Above-ground		
5	....	750	40	500,000	45,000	100	266,000 †
10	75,000	1,100	50	Unlimited	64,000 *	150	400,000 †
20	100,000	3,000	60	"	80,000 *	250	666,000 †
25	150,000	21,000	75	"	125,000 *	300	1,333,000 †
30	200,000	31,000	85	"	200,000 *	350	2,666,000 †

* May be increased 33% if provided with approved extinguishing apparatus. † Minimum distance may be 175 ft. if provided with approved extinguishing apparatus that also covers other parts of yard and system.

Care of Tanks.—Oil tanks should be cleaned at least once a year. Water and foreign material which settles out of the oil, if allowed to remain on the tank bottom, will accelerate corrosion. Large storage tanks should have a manhole for entrance for periodic examinations and cleaning. To insure that all oil vapors have escaped, before entering the tank, the manhole should be left open for several hours, and air circulation established by steam, compressed air, or a fan. The tank should be examined carefully, the bottom thoroughly cleansed, and all discolored or rusty spots scraped and painted with a compo-

sition paint, insoluble in oil or water, made especially for this purpose. Ordinary paint is unsuitable, being soluble in oil.

OIL PUMPS.—The primary purpose of an oil pump in connection with oil burners is to draw oil from the storage tank by suction and deliver it to the burner. A secondary purpose, sometimes, is to deliver the oil under sufficient pressure to produce the atomization necessary for combustion. (See page 4–50.)

PIPING SYSTEMS depend on the design of burner, storage system, grade of oil and the requirements of local authorities.

Heavy Oil Systems.—The principal difference between the piping for light and heavy oils is the use of preheaters. Consult burner manufacturers for detailed requirements for individual types of burners. The kind and amount of equipment necessary depend on design of burner, grade of oil used, location of tank, character of load, and degree of automatic operation required. Fig. 3 shows a typical heavy oil piping layout.

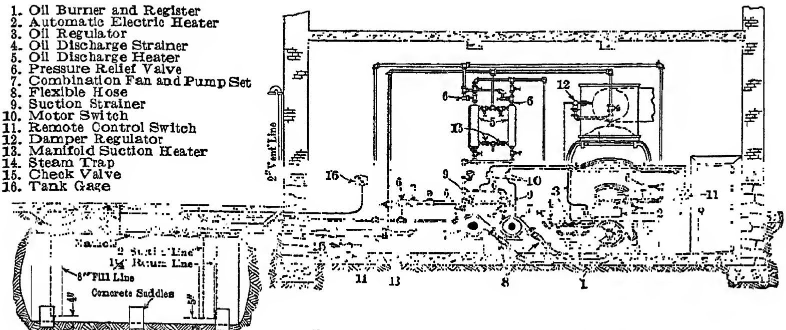

FIG. 3. Typical Heavy Oil Piping Layout

Fill Lines.—Not less than 2-in. pipe should be used for light oils (No. 1); for heavy oils (No. 6), 6-in. or 8-in. pipe should be used. A pipe too large is better than one too small. The fill line for any storage tank should pitch from the fill box to the tank A trap should be provided, either directly inside or outside of the tank, or the fill line sealed by ending it in the tank below the bottom of the suction line. The fill line always should be connected at the low end of the tank, and never cross-connected to the vent pipe.

Vent Pipe.—All fuel oil storage tanks must be vented. The size of the vent pipe should be in proportion to the size of the fill line, and never should be less than 1 1/4-in. pipe. The vent line should be without traps, pitched up from the tank and connected near the high end. It should be installed with swing joints, and should not be cross-connected with any line other than a vent. The vent pipe terminal should be visible from the fill box, should be weather-proof and preferably without screens.

The Suction Line is a most important part of an installation. Between buried storage tanks and the building wall, it should pitch toward the tank, and always should have swing joints. Usually a foot-valve is advisable on the suction line inlet in the tank, about 2 in. above the bottom of the tank for light oil, and 4 in. above for heavy oil. A testing tee should be in the suction line to permit testing at any time.

Strainers.—Every oil line to the burner should have a suitable strainer, either suction or discharge. If the plant is shut down regularly single strainers are satisfactory, but for continuous operation, duplex strainers are advisable. The size of mesh depends on grade of oil used, location of strainer and design of burner. In general, the mesh should not be finer than necessary to protect equipment in the portion of the line where the strainer is located. For light oils, suction strainers are 30 mesh or finer; discharge strainers 40 mesh or finer. For heavy oil, suction strainer meshes range from 8 to 30; discharge strainers from 20 to 30 mesh. The area of strainer surface is of equal importance as the size of mesh. Suction strainers should be at least double the area of the suction line. Discharge strainers should have at least 1 sq. in. area per gallon of oil burned per hour.

PREHEATERS may be classified as: 1. Use, *i.e.*, tank, suction, discharge, auxiliary. 2. Construction, *i.e.*, manifold, coil, multipass, film. 3. Heating medium, *i.e.*, steam, hot water, electric.

Tank Heaters are used only where oil temperature in the tank is so low that oil cannot be pumped. Tank heaters sometimes are called suction heaters. Often, however, for

long suction lines a manifold heater is used to insure a steady flow of oil. Steam or hot water furnishes heat, depending on the grade of oil, the temperature required, and the size of heater. Steam generally is used, but some city ordinances require hot-water heaters to insure control of maximum temperature.

Discharge Heaters reduce the viscosity of the oil to permit atomization. They always should be used for oils Nos. 5 and 6, regardless of burner design. With pressure atomizing burners they often can be used to advantage with No. 4 oil. At least two discharge preheaters should be provided, each of sufficient capacity to carry the normal load, to permit cleaning and inspection without interrupting service. For wide variations in load, several heaters should be installed, to be cut in and out as needed. The best practice uses one heater at maximum capacity rather than several in parallel or partial capacities. To avoid excessive heat losses, discharge heaters should be placed as close to the burner as structural conditions will permit.

Auxiliary Heaters.—Auxiliary electric heaters, used to preheat heavy oils, permit starting when the system is cold. This type of heater also is incorporated in full automatic heavy oil burners. It requires approximately 0.0146 kw-hr. to raise 100 lb. of oil 1° F. in one hour. This type also is incorporated in full automatic heavy oil burners.

Oil Temperature.—The temperature required for the oil depends on the design of burner, and viscosity of the oil. Table 11 gives the range of temperatures commonly used. The table is based on gravity and should be used only as an approximation. The correct temperature required to *reduce the viscosity* of the oil to from 70 sec. to 140 sec. Saybolt Universal should be determined by test, or A.S.T.M. specification D341-32T, and maintained. Gravity is not an accurate index to viscosity. Because of operating difficulties in pumping and atomizing, oil should not be heated above its flash point.

Table 11.—Approximate Preheating Temperatures for Fuel Oil

Gravity, A. P. I.	Temperature, deg. F.	Gravity, A. P. I.	Temperature, deg. F.	Gravity, A. P. I.	Temperature, deg. F.
10–12	275–325	16–18	150–200	22–24	160–200
12–14	220–275	18–20	140–160	24–26	70–80
14–16	175–250	20–22	100–140	....	....

Preheaters designed for steam generally should have from 0.15 to 0.3 sq. ft. of heating surface for each gallon per hour capacity, depending on the grade of oil used and design of heater. So many variables are involved, *i.e.*, types of heaters (manifold, coil, multipass and film), heating mediums (high- and low-pressure steam, hot water), temperature required by service conditions, grade of oil, types of burners, etc., that preheaters either should be selected on burner manufacturers' recommendations, or designed as a heat exchanger on the basis of data applying to specific installation requirements. Heaters should be examined regularly to detect leaks between the oil and steam passages. Such leaks usually can be detected by examining a sample of condensate from the heater. Heaters should be cleaned regularly, using steam in the oil passes and boiler compound in the steam passes. After disconnection or repair, heaters should have a hydrostatic pressure test before being put in service. Good practice provides discharge heaters with a by-pass relief valve to the suction or return line, to prevent damage by abnormal pressures if the oil lines of the heater are cut out and the steam left on.

TEST CODES.—All data, observations and calculations necessary for testing stationary steam generating units are given in the A.S.M.E. Boiler Test Code. See p. 16–13. For low-pressure boilers, use the A.S.H.V.E. Standard Code for Testing Steam Heating Boilers Burning Oil Fuel.

4. FLOW OF OIL*

The flow of oil in pipes is influenced by the viscosity of the oil, which varies with temperature, and by the character of flow, *i.e.*, streamline or viscous, and turbulent.

VISCOSITY is that property of fluids by which they resist an instantaneous change of shape or arrangement of their molecules.

Absolute Viscosity is defined as the force required to move a plane surface of the fluid, of 1 sq. cm. area, parallel to another plane surface of the fluid at 1 cm. distance from the first, and with a relative velocity of 1 cm. per sec. The unit of viscosity is the poise = 1 dyne-cm. per sec. per sq. cm. The centipoise = 0.01 poise usually is used in engineering calculations. The viscosity of water at 68° F. is 1 centipoise. The temperature at which viscosity is measured always should be stated. The symbol of absolute viscosity is μ.

To convert viscosity as measured in poises to viscosity as measured in English units,

* Revised by Robert Thurston Kent.

the following conversion factors are used: 1 poise = 100 centipoises = 0.0672 lb. mass per ft. per sec. = 0.0672 poundal-sec. per sq. ft. = 0.00209 lb. force sec. per sq. ft.

Kinematic Viscosity, whose symbol is y, is the ratio of the absolute viscosity μ, to the density ρ, of the fluid, *i.e.*, $y = \mu/\rho$. Kinematic viscosity is more useful in engineering work, as it can be determined directly from viscosimeter readings (see p. 4–46) by using the equations of Table 12. Kinematic viscosity also is defined as the ratio of absolute viscosity to specific gravity. The former definition, however, is preferred.

Table 12.—Equations for Converting Viscosimeter Readings to Kinematic Viscosity

t = time of flow seconds

Viscosimeter	Metric Units y = sq. cm. per sec.		English Units y = sq. ft. per sec.	
Saybolt Universal *	$y = 0.0022\,t - (1.8/t)$.	[1]	$y = 0.00000237\,t - (0.00194/t)$.	[1a]
Engler	$y = 0.00147\,t - (3.74/t)$.	[2]	$y = 0.00000158\,t - (0.00403/t)$.	[2a]
Redwood	$y = 0.0026\,t - (1.72/t)$.	[3]	$y = 0.00000280\,t - (0.00185/t)$.	[3a]

* Saybolt Furol = (Saybolt Universal/10) Approx. See Table 2.

Relative Viscosity is the ratio of the absolute viscosity of a fluid to that of water. The symbol of relative viscosity is Z.

Density, ρ, is defined as the mass per unit volume. It also is defined as the weight per unit volume, as determined by balancing against standard weights, and not as measured on a spring balance.

Variation of Viscosity with Temperature.—The absolute viscosity of petroleum oils varies with temperature, decreasing as temperature increases. Between 32° and 400° F. the variation will be in a straight line when plotted on logarithmic paper.

STREAMLINE AND TURBULENT FLOW.—In streamline or viscous flow, each particle of fluid moves in a direction parallel to the axis of the channel or pipe. In a pipe, the velocity of flow increases from a minimum at the circumference to a maximum at the center. The average velocity over the cross section of the pipe is one-half the maximum velocity. The velocity at any radius r is

$$V = \{(P_1 - P_2)/4L\mu\} \times \{(D^2/4 - r^2\} \quad . \; . \; . \; . \; . \; . \; . \; . \quad [4]$$

where in any homogeneous system of units V = velocity; r = radius; P_1 and P_2 = higher and lower pressures, respectively; L = length; μ = absolute viscosity; D = diameter. If velocity distribution be plotted with radii as ordinates, and velocities as found by equation [4] as abscissas, the resulting curve is a parabola with its vertex in the axis of the pipe.

When the velocity increases beyond a certain value the flow ceases to be streamline and becomes **turbulent.** The point at which streamline flow ceases is determined by the Reynolds number (see below). Streamline flow usually exists with values of Reynolds numbers below 2000. For values between 2000 and 3000, the flow is unstable, and this range is called the *critical velocity.* The point at which flow changes from streamline to turbulent is the *critical velocity region.* Flow is turbulent when the Reynolds number is above 3000. Flow in the critical range produces excessive pressure drops without corresponding increases in volume discharged. Oil pipes, therefore, should be so designed as to avoid flow in the critical region.

Reynolds Number.—Prof. Osborne Reynolds in 1874 showed that the critical velocity varies directly as the absolute viscosity of the fluid and inversely as the pipe diameter and the density of the fluid. These relations are expressed in the Reynolds number. For a discussion of Dimensional Analysis, on which Reynolds numbers are based, see Eshbach, Handbook of Engineering Fundamentals, Sect. 3 (John Wiley & Sons), and Barnard, Ellenwood and Hirshfeld, Elements of Heat-Power Engineering, Part III, p. 795 (John Wiley & Sons).

$$\text{Reynolds Number} :: \frac{\text{diameter} \times \text{velocity} \times \text{density}}{\text{absolute viscosity}} = \frac{D\,V\,\rho}{\mu} \quad . \; . \; . \quad [5]$$

$$= \frac{\text{diameter} \times \text{velocity}}{\text{kinematic viscosity}} = \frac{DV}{y} \quad . \; . \; . \; . \; . \; . \; . \; . \quad [6]$$

In computing a Reynolds number a homogeneous system of units should be used if formulas [5] and [6] are to be applied directly, for example, metric dimensions and viscosities in poises or centipoises. If dimensions are expressed in the English system, the conversion factors given above under definition of absolute viscosity must be introduced.

Example.—Given a liquid of viscosity 30 centipoises (=0.3 poise), density 0.9 gram per cu. cm., flowing at a velocity of 300 cm. per sec. in a pipe 10 cm. diam.; Reynolds number = $(10 \times 300 \times 0.9)/0.3 = 9000$.

In English units, density = $0.9 \times 62.43 = 56.187$; velocity = $300 \times 0.03281 = 9.843$ ft. per sec.; diam. = $10 \times 0.03281 = 0.3281$ ft. Conversion factor = 0.0672. Reynolds number = $(0.3281 \times 9.843 \times 56.187)/(0.3 \times 0.0672) = 9000$.

VOLUME OF FLOW.—In the following discussion, based on article by Prof. W. F. Durand in Day's Handbook of the Petroleum Industry (John Wiley & Sons), the units are all in the English system, *viz.*, pounds, feet, and for viscosity, poundals.

Notation.—μ = absolute viscosity, poundal-sec. per sq. ft. = 1488 centipoises; ρ = density, lb. per cu. ft.; D, d = diameter, ft. and in., respectively; L = length, ft.; V = velocity, ft. per sec.; P_1, P_2 = higher and lower pressures, respectively, lb. per sq. ft.; h = head, ft. = $(P_1 - P_2)/\rho$ lb. per sq. ft.; g = acceleration due to gravity = 32.2; R = Reynolds number = $DV\rho/\mu$; K = a constant.

The head causing the flow of oil is

$$h = \phi \frac{[illegible]}{\mu} \times \frac{[illegible]}{D} \frac{[illegible]^2}{2g} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [7]$$

If $\phi(DV\rho)/\mu$ be put equal to f, equation [7] corresponds to the familiar D'Arcy equation for the flow of water

$$h = f(L/D)(V^2/2g) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [8]$$

For a given value of $R = (DV\rho/\mu)$ the value of f in equation [8] will be constant, irrespective of the individual values of D, V, ρ and μ. Table 13 gives values of f for various values of R. If R be expressed as $DV \times (\rho/\mu)$, the value of (ρ/μ) can be obtained from the readings of a Saybolt Universal viscosimeter by means of Table 14. This table gives the reciprocals of the values of $y = \mu/\rho$ as computed by formula [1a]. The value of R, and consequently of f, for any combination of values of D and V thus is easily determined from the viscosimeter reading.

The volume of oil flowing depends on the area of the pipe and the velocity. From equation [8]

$$\sqrt{[illegible]}$$

where K is a constant depending on the diameter of the pipe and the value of f. Values of K are given in Table 15. Values intermediate to those given in the table can be obtained by plotting on logarithmic paper any two values of K for a given pipe diameter and drawing a straight line between the points. Intermediate values of both K and f then can be read. Volume, in cu. ft. per sec., then is

$$Q = VA = \frac{[illegible]}{4} \quad [10]$$

Values of $A = (\pi D^2/4)$ may be taken from Table 15. The volume flowing measured in any other units is

$$[illegible] \quad [11]$$

where C is a constant whose value is as follows.

Unit...	Cu. ft. per min.	Cu. ft. per hr.	U. S. gal. per min.	U. S. gal. per hr.	Barrels (42 gal.) per hr.	Barrels (42 gal.) per day
C......	60	3600	448.8	26,928	641.1	15,386

If L is taken in miles instead of feet, the constant C becomes

$$C_1 = C/\sqrt{5280} = 0.013762C.$$

The only uncertain factor is the value of f. Emory Kemler (*Trans.* A.S.M.E., HYD-55-2, 1933) in an exhaustive study of the work of previous investigators, concludes: 1. Value of f is independent of the fluid flowing for identical values of R. 2. For brass pipe, f varies only about ±5% from an average value and is substantially independent of pipe size and fluid flowing for identical values of R in the range usually met in practice. 3. For steel pipe, f varies about ±10% from an average value, and varies with size because roughness increases with pipe diameter. 4. If roughness is not large enough to cause contraction and enlargement losses, f never exceeds 0.054. Kemler further states that the effect of diameter on flow is important, since f varies as D^5. Hence, a small change in D produces a large change in f. For example, if a value of $D = 1$ is used in design, whereas the actual value is 0.9, the pressure drop will be about 70% greater than the value based on $D = 1$.

Streamline Flow.—The value of f for streamline flow in circular horizontal pipes has been determined experimentally to equal $64/R = 64\mu/DV\rho$. If this is substituted in equation [8] we have

$$h = (32\mu LV)/gD^2\rho \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [12]$$

which is known as Poiseuille's law. It indicates that for streamline flow in horizontal

pipes the drop in pressure varies directly as the absolute viscosity, average velocity and length of pipe, and inversely as the square of the pipe diameter.

Turbulent Flow.—The value of f in turbulent flow depends almost entirely on the roughness of the pipe. There has been no rational method of evaluating roughness, and heretofore the selection of f for a given set of conditions has been largely a matter of experience and judgment. R. J. S. Pigott (The Flow of Fluids in Closed Conduits, *Mech. Engg.*, Aug. 1933) has evolved a method which, while empirical, is well borne out by experimental data. Basing his method on Kemler's studies (see above) Pigott

Table 13.—Values of f Corresponding to Various Reynolds Numbers

Streamline Flow		Turbulent Flow					
$DV\rho/\mu$	f	$DV\rho/\mu$	f	$DV\rho/\mu$	f	$DV\rho/\mu$	f

derived the curves, Fig. 4, which give the value of f for various classes of pipe with various degrees of roughness. Kemler has shown that roughness varies with diameter and character of pipe. From his data, Pigott prepared Table 16, which shows the effect of these two variables and refers the reader to the proper curve in Fig. 4, from which to select a value of f consistent with the given conditions.

Pigott bases his method on the assumption that the roughness of the surface has the effect of entangling a film of the fluid somewhat thicker than the depth of the projecting rough portions, flowing at low speed close to the wall of the pipe, and thereby virtually reducing the diameter of the pipe. Since the flow varies as D^5, a small increase in roughness will cause a large variation in flow. For a given pipe diameter, the thickness of the film would decrease with increased speed or density, and would increase with increase of viscosity and roughness. Pigott concludes that the values of f approach the values for smooth pipes as the diameter increases, and must lie between the smooth pipe curve and a constant value of 0.054 for entirely rough surfaces.

5. GASOLINE AND KEROSENE

PETROLEUM NAPHTHA is a generic term applied to refined, partly refined or unrefined petroleum products, and liquid products of natural gas, not less than 10% of which distills below 347° F., and not less than 95% of which distills below 464° F., when subjected to distillation in accordance with the A.S.T.M. standard method. (A.S.T.M. designation D86.)

Gasoline is defined (A.S.T.M. designation D288-31T) as a refined petroleum naphtha which by its composition is suitable for use as a carburant in internal combustion engines. For gasoline specifications see Federal Specification Board requirements. Also see Edgar, Boyd and Hill, The Meaning of the Gasoline Distillation Curve, *Trans.* A.P.I., 1930.

While gasoline and kerosene are not entirely uniform in make-up, there is substantial agreement among producers and consumers as to their general characteristics.

The fuel-air ratio for gasoline and kerosene varies between 14 and 15 lb. of air per pound of fuel.

Commercial Gasoline is a mixture of liquid hydrocarbons distilling between about 100° and 400° F. It usually is a composite of: *a*. Straight run gasoline, *i.e.*, the portion of crude oil boiling up to 400° F.; *b*. Cracked gasoline, *i.e.*, the same portion of the product made by thermally decomposing heavy oils; *c*. Casinghead or natural gasoline, *i.e.*, the liquid hydrocarbons carried as vapor in natural gas. The sulphur content usually is limited by specification to 0.1%, and the proportion of elements other than carbon and hydrogen is negligibly small. The elementary composition by weight is, in general, not far from carbon, 85.7%, hydrogen, 14.3%. The refined product on the market usually is free of water, acid compounds, gum or other deleterious constituents.

Gasoline ordinarily is graded by volatility and anti-knock value (octane number; see p. 14–68) into motor, premium and aviation grades, the latter being used in airplanes. Typical samples of these grades may have characteristics given in Table 17.

Typical significant properties of gasoline are: Volume as vapor at 32° F. and 760 mm., 3.6 cu. ft. per lb., 22.3 cu. ft. per gal.; air required for combustion of 1 lb. of gasoline, 15.3 lb.; calorific value = 18,254 + (39.6 × deg. A.P.I.) = 20,600 B.t.u. (approx.); vapor pressure at 100° F. (Reid method, A.S.T.M. D323-32T), 7–8 lb. (summer), 9–10 lb. (winter); surface tension against air, 25–28 dyne-cm.;

$$\text{specific heat} = \{(t^\circ\text{ F.} + 670)(2.10 - \text{sp. gr.})\}/2030 = 0.52 \text{ (approx.)};$$

heat of vaporization (approx.), 130 B.t.u. per lb., 150 for light fractions, 100 for heavy ends; electrical conductivity, (2 to 4) $\times 10^{-14}$; coefficient of thermal expansion per deg. F., 0.0006–0.0007 (see Bur. Stds. Circular 154 for tables of calculated results).

EXPLOSIVE MIXTURES OF GASOLINE.—Mixtures of air and gasoline vapor containing from 1.5 to 2.5% of gasoline are explosive. (Tech. Paper 115, U. S. Bureau of Mines.)

SPECIFIC VOLUMES of petroleum products completely vaporized at one atmosphere pressure are given in publication No. 97 of the U. S. Bureau of Standards. Table 18 gives values at 60° F. for products having a specific gravity range of 0.6690 to 0.7796 to include both gasolines and kerosene.

Table 18.—Specific Volume of Petroleum Products at 60° F. and 1 Atmosphere Pressure
(U. S. Bureau of Standards)

Vapor, cu. ft. per lb.	2.8	3.1	3.4	3.7	4.0	4.3	4.6

Petroleum Naphthas for Special Purposes, as dry cleaning and paint thinning, usually are made up of materials corresponding to the higher-boiling half of gasoline. The boiling range of dry-cleaning solvent may be from 250° or 280° F. to 400° F., and the flash point is around 100° F. The physical properties correspond to those of gasoline, making allowance for the shift in molecular weight.

KEROSENE is defined (A.S.T.M. designation D288–31T) as a refined petroleum distillate having a flash point not below 73° F. as determined by the Tag closed tester (see A.S.T.M. designation D56), and suitable for use when burned in a wick lamp.

Kerosene is a higher boiling product than gasoline or the special naphthas. The significant physical properties of a typical product are, in general, as follows: Specific gravity, 0.8155; A.P.I. gravity, 60° F., 42.0; flash point, closed tester, 132° F.; coefficient of thermal expansion, per deg. F., 0.0005; viscosity, centipoises, 1.9; heat of vaporization, 85 B.t.u. per lb.; surface tension, 30 dyne-cm.; assay distillation: overpoint, 347° F.; 10%, 381° F.; 50%, 436° F.; 90%, 500° F.; end, 539° F.

Specifications for Kerosene for general illuminating purposes for U. S. Government are given in Tech. Paper 323, U. S. Bureau of Mines as: Flash point, min. 100° F.; flock test, negative; sulphur, max., 0.125%; distillation end point, max., 625° F.; cloud point, negative at 5° F.; the oil to be free from water, glue and suspended matter, and to burn readily and freely for 16 hr.

Kerosene Distillates are used to some extent as fuel oils for small furnace installations. The product employed for lamps and wick burners must be much more highly purified; the extent of purification and suitability are verified by long-time burning tests.

ALCOHOL.—Denatured alcohol is a grain or ethyl alcohol, C_2H_5OH, mixed with a denaturant in order to make it unfit for beverage or medicinal purposes. The various governments provide definite formulas for completely denatured alcohols. For information refer to U. S. Internal Revenue Department, or other authorities having jurisdiction. The denaturants generally used in varying proportions are methyl or wood alcohol (CH_4O),

benzol and pyridin. The alcohol which it is proposed to manufacture under the present law (1935) is ethyl alcohol. This material seldom, if ever, is obtained pure, it being generally diluted with water and containing other alcohols when used for engines.

The products of complete combustion of alcohol are H_2O and CO_2. Under certain conditions, with an insufficient supply of air, acetic acid is formed, causing rusting of the parts of an alcohol engine. This may be prevented by addition of benzol to the alcohol.

SHALE OIL is obtained by the destructive distillation of oil-shale. This is a compact rock of sedimentary origin, with an ash content of more than 33%. It contains organic matter yielding oil when destructively distilled, but not appreciably when extracted with the ordinary solvents for petroleum. At present (1935) shale oil is not important as a commercial product.

COAL TAR AND TAR OIL. (Industrial Furnaces, W. Trinks, John Wiley & Sons, N.Y.).—Coal tar is a product of the destructive distillation of bituminous coal carried out at high temperature. A typical composition of tar is: C, 86.7%; H, 6.0%; N, 0.1%; S, 0.8%; O, 3.1%; ash, 0.1%; water, 3.2%. The black color is due to free carbon in suspension (about 4%). The high heating value equals 16,340 B.t.u. per pound. The viscosity is about 140 Saybolt seconds at 140° F. Coal tar weighs 9.5 lb. per gal. The above analysis shows tar to have almost the same chemical composition as the combustible matter of the coal from which it is made. Tar principally is used in reheating and open-hearth furnaces of steel works. It is not easily obtainable in the open market. Since it is a by-product, its cost price is more or less arbitrary.

Liquefied Petroleum Gas as an industrial fuel for heating furnaces and similar purposes is described by R. W. Thomas (Trans. A.S.M.E., FSP-52-21, 1930). Such gas is the vapor of propane or butane, which are obtained in the cracking of oil for motor fuel and other products. The physical properties of commercial grades of the two gases are given in Table 21.

Table 21.—Properties of Propane and Butane.

	Vapor Pressure, lb. per sq. in. at			Specific Gravity		Cu. Ft. of Gas		Boiling	Heating Value, B.t.u.		
	70° F.	100° F.	130° F.	Liquid	Gas	Per lb.	Per gal.	Point, deg. F.	Per lb.	Per gal.	Per cu. ft.
Propane..	120	195	300	0.509	1.523	8.49	36	—45	21,650	91,800	2550
Butane...	33	65	110	0.576	1.95	6.7	32	12	21,500	102,400	3200

Commercial butane is less volatile than propane and is better adapted to industrial use. It will evaporate at temperatures down to 32° F. when supplied with its latent heat of evaporation, 170 B.t.u. per lb. Ordinarily it is vaporized in a multi-tubular vaporizer, by hot or cold water or steam. The vapor may be piped any distance at moderate pressure if it is not cooled below the dew point, 26° F. It is burned in burners that either premix air and vapor or which draw the vapor in by flow of the air supply. The advantages of this fuel are ease of temperature regulation and furnace atmosphere control, the absence of sulphur compounds, dust and water in the furnace, together with smaller pipe sizes than are required for manufactured or natural gas. It is competitive with manufactured gas for practically all uses but not with natural gas.

Vegetable Oils as Internal Combustion Engine Fuel. (*Engineer*, Mar. 11, 1921.)—Tests of internal combustion engines using palm oil or cotton seed oil showed the following fuel consumption: 265 grams per cheval-heure (1 cheval-heure = 0.9863 Hp.-hr.) in a 4-cycle, 25-Hp. engine; 320 grams per cheval-heure in a 2-cycle, 168 Hp. engine; 285 grams per cheval-heure in a 2-cycle, 33-Hp. engine. The calorific value of palm oil and cotton seed oil averaged 9350 calories per kg. Thermal efficiencies were 25.9, 21.45 and 24.1%.

GASEOUS FUELS *

The gaseous fuels commonly used in industry are producer gas, blast furnace gas, coke oven gas, acetylene and hydrogen. For heats of combustion of gases, see p. 4-05.

PRODUCER Gas.—See p. 13-03.

ILLUMINATING Gas.—See p. 4-67.

GAS ANALYSES BY VOLUME AND WEIGHT.—To convert an analysis of a mixed gas by volume into analysis by weight: Multiply the percentage of constituent gas by its relative density, *viz;* CO_2 by 11, O by 8, CO and N each by 7, and divide each product by the sum of the products. Conversely, to convert analysis by weight into analysis by volume, divide the percentage by weight of each gas by its relative density, and divide each quotient by the sum of the quotients.

EXPLOSIVE MIXTURES OF GASES (Tech. Paper 39, U. S. Bureau of Mines.)—Mixtures of methane and air containing less than 5.5% or more than 12.8% methane

* Staff Revision.

will not explode. The explosive power is greatest when the proportion of methane is about 9.5%. The limit of inflammability is about 30% methane. The mixture between this proportion and explosibility burns quietly. A mixture of one volume methane and 955 volumes of dry air will ignite at 1200° F. The pressure developed by this mixture ignited in a closed space is 102.5 lb. per sq. in

NATURAL GAS.—The principal constituent of natural gas is methane CH_4, but the composition and calorific value varies between wide limits, depending on the locality. See Table 1.

* Contained also 1.2% hydrogen sulphide (H_2S).

BLAST-FURNACE GAS AND COKE-OVEN GAS are given off in the operations of blast furnaces and coke ovens. Typical analyses of these gases (F. E. Leahy, *Yearbook*, Am. I. & S. Inst., 1929) are as follows:

	CO_2	O_2	CO	H_2				H_2S	per cu. ft.
Blast-furnace gas....	12.4	0.0	26.6	2.2	0.4	58.4	...	...	97.1
Coke-oven gas......	1.4	0.2	5.9	57.3	26.9	4.7	3.0	0.6	537.0

These gases, in steel plant operation, are mixed to give a gas of the desired heat content for various operations. Table 2 gives the heat content of various mixtures.

Leahy gives the heat requirements of gas for the various furnaces, B.t.u. per cu. ft., as follows: Billet-heating, 350; box-anneal, 200; coke ovens, 100–250; open-hearth, 250–350; sheet and pair, 250; soaking pits, 150; tin pots, 250.

A mixture of coke-oven and blast-furnace gas often can be substituted profitably for producer gas or other fuels in steel plants. According to Leahy, the order of replacement, in general, should be first the lower-temperature furnaces, excepting welding, melting and

open-hearth, and the higher-temperature furnaces last. If only the fuel replacement value is considered, especially if the gas producer plant cannot be operated economically, the open-hearth should be supplied first with the mixed gas. In determining desirability of substituting mixed gas for present fuel, the replacement value of the latter should be measured against its heat value, by a study of present cost against expected cost. An example of such a study is given in Leahy's paper above cited. B. F. Entwisle, in a discussion of this paper, states that as blast-furnace gas is produced uniformly, it is best burned in furnaces that require fuel regularly and uniformly. Purchased fuels should be replaced by blast-furnace and coke-oven gas in the order of their cost, the most expensive first. Based on these considerations, the order of use of the mixed gas would be: 1. Base steam load, including blower and power load of blast furnaces and coke ovens (Sunday load only). 2. Coke oven heating. 3. Open-hearth furnaces. 4. Soaking pits. 5. Reheating furnaces. 6. Week-day steam and power load.

Leahy states that open-hearth furnaces using liquid fuel, natural gas or coke-oven gas require alteration if they are to use a mixture of blast-furnace and coke-oven gas. The checkers must be sealed to prevent leakage through walls and roof. Preheating the blast-furnace gas to 1200 deg. F. and enriching it with coke-oven gas may eliminate necessity of sealing. Preheating of the gas gives a higher flame temperature than preheating the air to the same temperature. Blast-furnace gas is non-luminous, and must be combined with other fuels to be given luminosity.

C. R. Meissner (*Yearbook* Am. I. & S. Inst., 1932) describes an extremely flexible arrangement for the utilization of blast-furnace gas and coke-oven gas at the plant of the Weirton Steel Co. Of 198,000,000 cu. ft. of blast-furnace gas produced daily, 55,000,000 cu. ft. are used in the blast-furnace stoves, 43,000,000 cu. ft. are used for under-firing the by-product coke ovens, the balance for general metallurgical furnaces. Of 26,300,000 cu. ft. of coke-oven gas, produced by 111 ovens, 16,300,000 cu. ft. are available for mill use when the coke-oven gas is used for under-firing the coke ovens. When blast-furnace gas is used under coke ovens, 23,000,000 cu. ft. of coke-oven gas are available for mill use. The heat consumption per pound of coal coked was: With coke-oven gas, 1101 B.t.u.; with blast-furnace gas, 1118 B.t.u. The blast-furnace gas gave a more uniform quality of coke.

A steam plant using blast-furnace gas at the Fairfield Works of the Tennessee Coal, Iron and R.R.Co. developed a boiler efficiency of 83% (F. G. Cutler, *Trans.* A.S M.E., FSP–54–2, 1932). The gas is cleaned in 11 Cottrell-type electric precipitators, which reduce the dust content (grams per cu. ft.) from 3.04, leaving dust-catcher, to 0.02, entering stoves, and 0.54 entering boiler furnaces. The average temperature of the gas entering the boiler was 470° F. The boilers used powdered coal as an auxiliary fuel.

The following average data are condensed from a table in the above paper:

B.t.u. per hr. in top gas, 739,150,000; gross boiler Hp. generated, 14,324; powdered coal burned per 24 hr., 31 tons; B.t.u. per hr. to steam at 82% efficiency, 572,980,000; B.t u. per hr. in powdered coal, 31,200,000; B.t.u. per hr. in blast furnace gas, 541,780,000; percent of top gas to boilers, 73.34; steam pressure, 324 lb. per sq. in.; superheat, 189° F.; boiler Hp. in service, 4383; percent of rating, 326. Surplus power generated in the plant is sold to the Alabama Power Co.

ACETYLENE, C_2H_2, consists of 92.3% carbon and 7.7% hydrogen It is a colorless, tasteless gas, of specific gravity 0.92. The commercial gas contains a small percentage of phosphoretted and sulphuretted hydrogen. It becomes liquid at a pressure of 700 lb. per sq. in. at 70° F. The pressure necessary for liquefaction varies directly with temperature, up to 98° F., which is the critical temperature. It cannot be liquified by any pressure at temperatures in excess of 98° F.

The heat of combustion of acetylene is 1475 B.t.u. per cu. ft. at 70° F. and 30 in. of mercury. Of this, 227 B.t.u. are endothermic. For complete combustion, 1 cu. ft. requires 11.91 cu. ft. of air. Its ignition temperature in air is 804° F., and in oxygen, 782° F.

Mixtures of air and acetylene in the proportions of from acetylene 3%, air 97% to acetylene 24%, air 76%, are explosive. The point of maximum explosibility is acetylene 7.7%, air 92.3%. Acetylene will explode of itself when ignited under a pressure of 15 lb. per sq. in. Danger of explosion is removed by absorbing the acetylene in acetone, which is itself absorbed by asbestos, kieselguhr or other non-inflammable substance.

Acetylene is produced by the combination of calcium carbide and water, in the proportions of 64 lb. CaC_2 and 36 lb. H_2O, to produce 26 lb. of acetylene. The chemical reaction is $CaC_2 + 2\,H_2O = C_2H_2 + Ca(OH)_2$. Calcium carbide is produced in the electric arc furnace from a mixture of finely divided and intimately mixed calcium oxide, or quicklime, and coke. The chemical reaction is $CaO + 3\,C = CaC_2 + CO$.

IGNITION TEMPERATURES OF GASES vary with the conditions under which they are burned. Table 3, compiled from the International Critical Tables, give ignition temperatures under several different conditions.

The methods used in determining the temperatures given in the table are as follows: A. Mixture passed through tube held at known temperature. B. Mixture rapidly admitted to bulb held at known temperature. C Bulb containing mixture rapidly heated to definite temperature. D. Mixture passed through small reservoir while temperature was raised until flame at exit tube ran back into it. E. Constituent gases heated separately in concentric tubes, gas from inner tube then being passed into gas in outer tube. F. Constituent gases heated separately and mixed in open. G. Mixture adiabatically compressed, and temperature calculated from final volume. H. Mixture adiabatically compressed, and temperature calculation based on final pressure, experimentally determined. Correct temperature lies between values calculated by G and H. J. Small drop of inflammable liquid dropped into air or O_2 at known temperature.

ILLUMINATING GAS

By Alfred E. Forstall

1. COAL-GAS AND WATER-GAS

COAL-GAS is made by distilling bituminous coal in either retorts or by-product coke ovens. Retorts are made of fire-clay or silica material, and are set either horizontally or vertically.

Horizontal retorts are usually long, semi-cylindrical, or ⌂-shaped, chambers and are either stop-end, *i.e.*, one end permanently closed, the other fitted with a cast-iron mouthpiece and lid; or throughs, with both ends open except for mouthpieces and lids. Internal cross-section varies from 14 × 24 in. to 16 × 28 in. Stop-end retorts usually are about 9 ft. long and hold 250 to 400 lb. of coal per charge of from 4 to 6 hr. duration. Through retorts are 11 to 22 ft. long and hold 400 to 1000 lb. per charge of from 4 to 12 hr. Retorts of either type are set in groups of 6 to 12. Such a group is called a bench, and is heated by a generator furnace or gas producer, usually using coke as fuel.

Vertical retorts are either rectangular or elliptical chambers; the internal cross-section at the top ranges from 33 × 10 in. to 103 × 10 in.; at the bottom it widens out to provide for expansion of the coal as it carbonizes in passing down through the retort. Length usually is 25 ft. Retorts are set in benches of from 2 to 8 retorts. Vertical retorts may be continuous or intermittent. Intermittent retorts are filled with from 2000 to 2400 lb. of coal and emptied of coke at regular intervals of 12 hr. In continuous retorts coal is fed at the top and coke discharged at the bottom continuously. Intermittent retorts have mouthpieces and lids at both ends. Continuous retorts have a coal hopper at the top and a coke chamber at the bottom.

By-product Coke Ovens are rectangular chambers, 13 ft., 6 in. to 42 ft. long, 8 to 13 ft. high, 12 to 18 in. wide. They carbonize charges of 4000 to 30,000 lb. of coke in 12 to 18 hr.

The volatile matter driven off when coal is exposed to heat consists of a mixture of fixed gases and vapors. During their passage to the outlet of the retort or oven some of these vapors are converted into fixed gases either by contact with the highly-heated walls of the retort or by exposure to heat radiated from the walls. For horizontal retorts or ovens this outlet consists of stand, bridge and dip pipes. The lower end of the latter is sealed in ammoniacal liquor in a horizontal pipe called a hydraulic main. From vertical retorts the gas is taken off at the upper end through a short pipe dipping into either a hydraulic, or a dry main. Coke ovens have take-off pipes at each end.

Cooling of the gas begins in this main, with a consequent condensation of a portion of the steam and hydrocarbon vapors to water and tar, respectively. The water, in forming, absorbs ammonia, which is present as a gas, and becomes ammoniacal liquor. Part of the tar is deposited in the hydraulic main, but the rest remains in the gas as a fog. To remove this the gas is passed through a frictional tar extractor, before its temperature is lowered below 100° F., and then goes to a condenser for further cooling. The condenser is a vessel traversed by iron tubes through which water flows, causing the deposition as light tar and ammoniacal liquor, respectively, of the excess of condensible hydrocarbon vapors and steam. The cooled gas passes through a washer, where it bubbles through water or ammoniacal liquor to remove the remaining light oils and a part of the ammonia and sulphuretted hydrogen, and through a scrubber, in which it travels in thin streams over wetted surfaces, where removal of the ammonia is completed. The gas then passes into the purifiers where the sulphuretted hydrogen is removed by means of hydrated ferric oxide. The gas then is measured and passed into storage holders.

COAL USED FOR GAS MANUFACTURE.—Coal generally used in gas making is caking-bituminous. When high illuminating value was important, it was necessary to enrich the gas produced from this coal by adding to it gas made from cannel coal, or carburetted water-gas. At the present (1935), illuminating value is not considered important in town gas, and coal-gas without any enrichment meets the ordinary requirements of Public Service Commissions.

Table 1 shows proximate analyses of various coals used for the manufacture of gas in the United States.

Table 1.—Proximate Analysis of Various Gas Coals Used in the U. S.

Name of Coal	Moisture	Volatile Matter	Fixed Carbon	Ash	Sulphur
	Percent	Percent	Percent	Percent	Percent
Pennsylvania-Westmoreland	0.93–1.51	33.02–36.33	56.09–58.87	5.99–9.07	0.76–1.81
West Virginia	0.80–1.35	36.92–38.60	53.70–55.36	6.37–6.90	0.90–1.40
Kentucky	1.17–4.25	35.60–36.89	56.84–60.30	2.02–2.93	0.53–1.74
Ohio-Hocking Valley	6.72	37.13	50.32	5.83	1.67
Oklahoma	3.87	35.73	50.05	10.35	1.99

THE PRODUCTS OF DISTILLATION from 100 lb. of average gas-coal vary according to quality of coal and temperature of distillation, but are about as follows: Coke 64 to 70 lb.; gas 15 to 19 lb.; tar 5 to 6 lb.; virgin liquor and ammonia 7 to 9 lb.; impurities and loss 3 to 5 lb.

WATER-GAS is obtained by passing steam through a bed of carbonaceous fuel heated to a temperature of at least 1800° F. The steam is decomposed, its oxygen being seized by the hot carbon, forming carbon monoxide and a small amount of carbon dioxide, and liberating hydrogen. The chemical reaction is $C + H_2O = CO + H_2$, or $2C + 2H_2O = C + CO_2 + 2H_2$, followed by a splitting up of the CO_2 as it comes into contact with more carbon. By weight, the theoretical gas, $CO + H_2$, consists of $C + O + H_2 = 28$ parts CO and 2 parts H_2, or 93.33% CO and 6.67% H_2. By volume, it consists of equal parts of CO and H. This theoretical gas never is made in practice and commercial water-gas always contains from 3% to 5% of CO_2, a small percentage of N, and a trace of CH_4. Water-gas, produced as above described, has a calorific value of about 300 B.t.u. per cu. ft., but no illuminating value. It may, however, be used for lighting by causing it to heat to incandescence some solid substance, as a Welsbach or other incandescent mantle.

CARBURETTED WATER-GAS.—An illuminating-gas, or a gas of higher calorific value, is made from water-gas by adding to it hydrocarbon gases, or vapors, which usually are obtained from the distillate of crude petroleum, known as gas-oil. With apparatus properly designed and operated, heavy fuel oil can be used as enricher.

A history of the development of carburetted water-gas processes, together with a description of the form of apparatus which at that time had been recently developed and which still remains the standard form, is given by Alex. C. Humphreys, in a paper Water-gas in the U. S. (Mech. Sec., British Assoc. for Advancement of Science, 1889).

The water-gas, or carburetted water-gas, process has two periods; (1) The "blow," during which air is blown through the fuel bed in the generator and the lean producer gas thus formed is completely burned in the carburetter and superheater, the other two vessels making up the generating apparatus, giving up a great portion of its heat to the firebrick checker-work contained in them, before passing out through a stack valve to the open air. (2) The "run," during which the air blast is stopped, the stack valve closed, and steam is passed through the incandescent bed of fuel. The resulting water-gas passes into the top of the carburetter where it meets a spray of a distillate of petroleum, as gas-oil, which is vaporized and carried by the water-gas through the carburetter and superheater, where the hydrocarbon vapors become converted into fixed illuminating-gases. From the superheater the combined gases are passed into a relief holder, which compensates for the intermittent nature of the process. From this holder it passes through condensers, tar extractors, purifiers, etc., into storage holders. No ammonia is formed, and no apparatus for its removal is required.

The specific gravity of carburetted water-gas increases with increase of the hydrocarbon gases, which give increased calorific value. It will vary between 0.54 and 0.70. For further description of both coal-gas and carburetted water-gas apparatus and operation see Morgan's American Gas Practice.

ANALYSES OF COAL-GAS AND CARBURETTED WATER-GAS.—No two samples of either coal-gas or carburetted water-gas have exactly the same composition. Table 2 gives percentage compositions by volume and by weight, which may be considered typical for coal-gas made in retorts and in coke ovens, and for carburetted water-gas of calorific value of 560 B.t.u. per cu. ft.

Characteristics of Constituents.—In burning the gas the CO_2, O and N are inert, and are so classed. The olefines, or illuminants, give the gas any illuminating power it may

Table 2.—Typical Composition of Coal-gas and Carburetted Water-gas

Specific gravity	0.42		0.37		0.64	
Calorific value, B.t.u. per cu. ft.	575		550		560	

have and contribute materially to its calorific value, as do also the CO, CH_4, C_2H_6, and H. Since the calorific value of blue water-gas is only about 300 B.t.u. per cu. ft., almost half the calorific value of carburetted water-gas comes from hydrocarbons added as oil gas.

CALORIFIC VALUE STANDARDS.—Neither coal-gas nor carburetted water-gas now is used in general practice for purposes in which its inherent illuminating value is important. Regulations for quality of gas that must be supplied deal only with its calorific value. The first calorific value standards, established in the U. S., called for gas of 600 B.t.u. per cu. ft., but at the present time (1935) the customary requirement is from 525 to 535 B.t.u. per cu. ft. The standard in Canada is 450 B.t.u. per cu. ft.

EFFICIENCY OF A WATER-GAS PLANT.—The practical efficiency of an illuminating water-gas setting is discussed in a paper by A. G. Glasgow (*Proc.* Am. Gaslight Assoc., 1890) from which the following is abridged:

The results refer to 1000 cu. ft. of unpurified carburetted gas, reduced to 60° F. The total anthracite charged per 1000 cu. ft. of gas was 33.4 lb., ash and unconsumed coal removed, 9.9 lb., leaving total combustible consumed, 23.5 lb., which is taken to have a fuel value of 14,500 B.t.u. per lb., or a total of 340,750 B.t.u.

The heat-energy absorbed by the apparatus is $23.5 \times 14{,}500 = 340{,}750$ heat-units $= A$. Its disposition is as follows: B, the energy of the CO produced; C, the energy absorbed in the decomposition of the steam; D, the difference between the sensible heat of the escaping illuminating-gases and that of the entering oil; E, the heat carried off by the escaping blast products; F, the heat lost by radiation from the shells; G, the heat carried away from the shells by convection (air currents); H, the heat rendered latent in the gasification of the oil; J, the sensible heat in the ash and unconsumed coal recovered from the generator.

The heat equation is $A = B + C + D + E + F + G + H + J$; A being known. A comparison of the CO in Table 3 shows that (280/434); or 64.5% of the volume of carburetted gas, is pure water-gas, distributed thus: CO_2, 2.3%; CO, 28.0%; H, 33.4%; N, 0.8%; total = 64.5%. 1 lb. of CO at 60° F. = 13,531 cu. ft. CO per 1000 cu. ft. of gas $= 280 \div 13.531 = 20.694$ lb. Energy of the CO $= 20.694 \times 4395.6 = 91{,}043$ heat-units $= B$. 1 lb. of H at 60° F. = 189.2 cu. ft. H per M. of gas $= 334 \div 189.2 = 1.7653$ lb. Energy of the H per lb. (according to Thomsen, considering the steam generated by its combustion to be condensed to water at 75° F.) = 61,524 B.t.u. In Mr. Glasgow's experiments the steam entered the generator at 331° F.; heat required to raise products of combustion of 1 lb. of H, *viz.*, 8.98 lb. H_2O from water at 75° to steam at 331° must be deducted from Thomsen's figure, or $61{,}524 - (8.98 \times 1140.2) = 51{,}285$ B.t.u. per lb. of H. Energy of the H, then, is $1.7653 \times 51{,}285 = 90{,}533$ heat-units $= C$. Heat lost due to sensible heat in the illuminating-gases, (temperature 1450° F.), and that of the entering oil (235° F.), is 48.29 (weight) $\times$ 0.45786 (sp. heat) $\times$ 1215 (rise of temperature) = 26,864 heat-units $= D$. The specific heat of the entering oil is approximately that of the issuing gas. The heat carried off in 1000 cu. ft. of the escaping blast products is

$$86.592 \text{ (weight)} \times 0.23645 \text{ (sp. heat)} \times 1474° \text{ (rise of temp.)} = 30{,}180 \text{ heat-units.}$$

The temperature of the escaping blast gases is 1550° F., and that of the entering air 76° F. But the amount of blast gases, by registration of an anemometer, checked by a calculation from the analyses of the blast gases, was 2457 cu. ft. for every 1000 cu. ft. of carburetted gas made. Hence the heat carried off per M. of carburetted gas is $30{,}180 \times 2.457 = 74{,}152$ heat-units $= E$.

Table 3.—Operation of a Water-gas Plant

		Composition by Volume	Weight per 100 cu. ft.	Composition by Weight	Specific Heat
I. Carburetted water-gas	$CO_2 + H_2S$	3.8	0.465842	0.09647	0.02088

III. Blast products escaping from superheater	CO_2	17.4	2.133066	0.2464	0.05342
	O	3.2	0.2856096	.0329	.00718
	N	79.4	6.2405224	.7207	.17585
		100.0	8.6591980	1.0000	0.23645
IV. Generator blast-gases	CO_2	9.7	1.189123	0.1436	0.031075
	CO	17.8	1.390180	.1680	.041647
	N	72.5	5.698210	.6884	.167970
		100.0	8.277513	1.0000	0.240692

Experiments made by a radiometer covering 4 sq. ft. of the shell of the apparatus gave figures for the amount of heat lost by radiation = 12,454 heat-units = F, and by convection = 15,696 heat-units = G.

The heat rendered latent by the gasification of the oil was found by taking the difference between all the heat fed into carbureter and superheater and total heat dissipated therefrom to be 12,841 heat-units = H. Sensible heat in ash and unconsumed coal is 9.9 lb. × 1500° × 0.25 (sp. heat) = 3712 heat-units = J.

$B + C + D + E + F + G + H + J$ = 327,295 heat-units, which subtracted from the 340,750 heat-units of the combustible consumed, leaves 13,455 heat-units, or 4% unaccounted for.

Of the total heat-energy of the coal consumed, or 340,750 heat-units, the energy wasted is the sum of items, D, E, F, G, and J, amounting to 132,878 heat-units, or 39%; the remainder, or 207,872 heat-units, or 61%, being utilized. Efficiency of the apparatus as a heat machine is 61%.

Five gallons, or 35 lb. of crude petroleum, were fed into the carbureter per 1000 cu. ft. of gas made; deducting 5 lb. of tar recovered, leaves 30 lb. × 20,000 = 600,000 heat-units as the net heating value of the petroleum used. Adding this to the heating value of the coal, 340,750 B.t.u., gives 940,750 heat-units, of which there is found as heat-energy in the carburetted gas, as in the table below, 764,050 heat-units, or 81%, which is the commercial efficiency of the apparatus, *i.e.*, ratio of energy contained in finished product to total energy of coal and oil consumed.

The heating power per M. cu. ft. of the carburetted gas is

C_3H_6*	146.0 × 0.117220 × 21222.0 =	363200
CO	280.0 × 0.078100 × 4395.6 =	96120
CH_4	170.0 × 0.044620 × 24021.0 =	182210
H	356.0 × 0.005594 × 61524.0 =	122520
		764050

The heating power per M. cu. ft. of the uncarburetted gas is

CO	434.0 × 0.078100 × 4395.6 =	148991
H	518.0 × 0.005594 × 61524.0 =	178277
		327268

* The heating value of the illuminants C_nH_{2n} is assumed to equal that of C_3H_6.

The candle-power of the gas is 31, or 6.2 candle-power per gallon of oil used. The calculated specific gravity is 0.6355, air being 1.

Since the efficiency of oil-gas production is greater than that of production of blue water-gas, the reduction in the percentage of oil-gas contained in carburetted water-gas as made at present as compared with that made in 1890, reduces the overall efficiency of the apparatus. On the other hand, the plant tested by Glasgow was not equipped, as such plants are now, with a waste heat boiler which recovers much heat otherwise carried off by escaping blast gases. Some English tests indicate an increase of efficiency of about 8.5% by use of waste heat boilers.

OIL-GAS.—Almost from the beginning of the business of manufacturing illuminating-gas hydrocarbon oils have been used for this purpose. These were originally the Scotch shale oils, and later, petroleum or some of its distillates, distilled in retorts similar to those used for the manufacture of coal-gas. This gas at first was employed as a substitute for and in competition with, other illuminating-gases. Later, for a number of years, it was used merely for the enrichment of coal-gas, the lighting of railway cars, etc., and the amount so used formed but a small proportion of the total amount of illuminating-gas made and distributed. In the last years of the 19th century the development of large oil fields caused petroleum to become in most of the Pacific Coast States, the cheapest available source of carbon and hydrocarbons. These conditions led to the development of a process, using crude petroleum or one of its heavier distillates as the sole raw material, for making a gas similar in composition to coal-gas but very different from the gas produced by the old method of distilling oil in retorts.

The form of apparatus most largely used for the manufacture of oil-gas consists of two cylindrical steel shells of equal diameter but different heights, lined with firebrick and filled to a greater or less extent with firebrick checker-work, similar to that used in the carburetter and superheater of a carburetted water-gas set. The shells are connected at the bottom by a throat piece. The heat required to gasify the oil is obtained by burning oil, sprayed into the apparatus by means of steam through sprays or burners entering the shorter vessel through the side, a short distance below its top. The oil is consumed by an air-blast entering the vessel through its top. A secondary air supply enters at the bottom of the taller vessel, and the products of combustion escape through a stack valve opening at the top of that vessel. When the apparatus has been heated to the proper gas-making temperature, that is, about 1800° to 2100° F., at the top of the shorter vessel, and about 1800° F. in the taller vessel, the blast is shut off, the stack valve closed, and oil is turned in through so-called gas-making burners at the top of the shorter vessel and either at the top or the bottom of the taller one, according to the type of apparatus. The " run " is continued until the temperature of the checker-brick has been reduced below that at which gas economically can be made. The oil then is shut off, and the apparatus purged with steam blown in through the oil burners.

Practically all of the illuminating-gas now (1935) made in the states of California and Oregon is made by this process, a more complete description of which can be found in Morgan's American Gas Practice.

CONSIDERATIONS AFFECTING THE CHOICE BETWEEN THE MANUFACTURE OF COAL-GAS OR CARBURETTED WATER-GAS.—Now that the illuminating value standard of quality has been abandoned and the calorific value standard can be met by coal-gas, the decision of the question of the kind of gas to be manufactured depends solely on conditions of prices of gas coal, coke, tar, and ammonia, anthracite coal, gas oil, and labor in any given locality. As a general proposition where there is a fair market for the residuals—coke, tar, and ammonia—of coal-gas manufacture, coal-gas can be produced at a lower material cost but with a higher labor cost than carburetted water-gas. The ground area required is much larger for coal-gas, and generally the investment in plant per 1000 cu. ft. of daily capacity is also greater for coal-gas. Before an intelligent decision can be reached as to the gas which can be most economically manufactured, it is necessary to study all the local conditions, and from this study determine the cost of each kind of gas, including both investment and operating charges.

The amount of gas to be made also has a great influence upon the relative economy of the two processes. Coal-gas must be manufactured continuously and, therefore, requires 24-hr. operation of the plant, while the operation of a carburetted water-gas plant can be suspended without detriment to the apparatus or undue increase in the cost of operation. For small plants it is, therefore, frequently more desirable to manufacture carburetted water-gas, making the total 24-hr. supply in a few hours, even under conditions where for manufacture on a large scale coal-gas would be more economical.

As far as generating apparatus only is concerned, Tables 4 and 5 show for continuous vertical retort coal-gas plants and for carburetted water-gas plants, respectively, the floor space required per 1000 cu. ft. of gas manufactured per day of 24 hr. The figures given for the carburetted water-gas plants include also that part of the condensing plant which would be immediately connected to the generating apparatus.

Table 4.—Space Required for Coal-gas Plant

Capacity of Plant, cu. ft.	Capacity of Unit, cu. ft.	Floor Space per 1000 cu. ft., sq. ft.	Capacity of Plant, cu. ft.	Capacity of Unit, cu. ft.	Floor Space per 1000 cu. ft., sq. ft.
500,000	125,000	4.00	2,500,000	312,500	2.60
750,000	125,000	3.75	3,000,000	312,500	2.60
1,000,000	250,000	3.25	3,750,000	375,000	2.50
1,500,000	250,000	3.00	4,500,000	375,000	2.50
2,000,000	250,000	2.75			

Table 5.—Space Required for Carburetted Water-gas Plant

Plant Capacity per Day, cu. ft.	Nearest Size Set	Capacity of Set per Day, cu. ft.	Ground Space One Set, sq. ft.	Square Feet per M. cu. ft. Generating Capacity	Ground Space, Spare Set, sq. ft.	Square Feet per M. cu. ft. Generating Capacity, spare set
200,000	4′ 0″	210,000	470	2.240	302	1.440
400,000	5′ 0″	480,000	630	1.310	490	1.020
800,000	6′ 0″	810,000	852	1.050	685	0.845
1,400,000	7′ 6″	1,470,000	1190	0.810	918	.625
2,000,000	8′ 6″	2,020,000	1465	.725	1160	.575
3,500,000	11′ 0″	3,500,000	2480	.710	1980	.566

In addition to the space required for the generating apparatus each type of plant requires space for additional condensing and for purifying, measuring and storage apparatus, as well as for the storage of manufacturing materials and residuals. The space required for the latter purposes is much larger in a coal-gas plant than in a carburetted water-gas plant.

FUEL VALUE OF ILLUMINATING-GAS.—The adoption of a calorific value standard of quality has made it important to have accurate means of determining the calorific value of illuminating-gas. This determination is made by a calorimeter, in which the heat of combustion of a measured quantity of gas is transferred to a measured quantity of water flowing at a constant rate through the calorimeter. The calorimeter most frequently used in the United States was originally designed by F. W. Hartley, but has been greatly modified and is now known as the Hinman–Junkers calorimeter. For a description of this calorimeter and the method of installing and operating it, see the Reports of the Committee on Calorimetry of the American Gas Institute (*Proc.* Am. Gas Inst.,

vol. iii, p. 285; vol. iv, p. 148), and also the Report of the Joint Committee on Calorimetry ... of the Second District. New York State and

B.t.u. per cu. ft.

At the price for which sold for industrial purposes, it furnishes only about 600,000 to 900,000 B.t.u. for $1.00, w th coal having a calorific value of only 12,000 B.t.u. per lb., and selling at $7.00 per ton of .b., there is furnished 3,429,000 B.t.u., or approximately four to six times as much as from the for the same cost. However, the greater efficiency with which gas can be utilized, together with the convenience, and in many operations, the increased capacity of apparatus and the decrease in the amount of spoiled work attending its use, makes gas for many industrial purposes a much cheaper fuel than coal.

2. FLOW OF GAS IN PIPES

The rate of flow of gases of different densities, diameter of pipes required, etc., are given by Pole in King's Treatise on Coal Gas, vol. ii, 374, as follows:

If d = diameter of pipe, in.;
Q = quantity of gas, cu. ft. per hour;
: length of pipe, yd.;
in.
of

$$d = \sqrt[5]{Q^2 sl/(1350)^2 h}$$

$$h = Q^2 sl/(1350)^2 d^5$$

Molesworth gives $Q = 1000\sqrt{d^5 h/sl}$.

* Formula: Equivalent volume = observed volume × {519.6/(t + 459.6)} × (B/30).

J. P. Gill (*Am. Gas-light Jour.*, 1894) gives $Q = 1291\sqrt{d^5h/s(l + d)}$. This formula is said to be based on experimental data, and to make allowance for obstructions by tar, water, and other bodies tending to check the flow of gas through the pipe.

Practically all problems concerning flow of gas in pipes are solved by gas flow computers of the slide rule type. A commonly used computer, is based on the Spitzglass formula, $Q = 3550\sqrt{\dfrac{hD^5}{SL\ \{1+(3.6/D)+0.03D}}$ where Q = quantity of gas, cu. ft. per hr.; h = loss of pressure, in. of water; S = specific gravity of gas, air being 1; L = length of pipe, ft.; D = internal diameter of pipe, in. The value of the coefficient of friction, used in deriving this formula, is $0.00285\ \{(1 + (3.6/D) + 0.03D)\}$, which was obtained by experiments on pipes of various diameters.

This formula gives slightly larger rates of flow than those given by Pole's formula under similar conditions. The figures in Table 7 were obtained by the slide rule flow computer mentioned above. All of the above formulas apply to low pressure gas, that is gas at a gage pressure of less than 1 lb. per sq. in. For gas at higher pressures, the Spitzglass formula is $Q = 66.5\sqrt{\dfrac{PAD^5}{SL\ \{1 + (3.6/D) + 0.03D\}}}$, where Q = quantity of gas, cu. ft. per hr. reduced to standard conditions of 30 in. pressure and 60° F.; P = drop of gage pressure, lb. per sq. in.; A = mean absolute pressure in pipe line, lb. per sq. in.; D = internal diameter of pipe, in.; L = length of pipe, miles; S = specific gravity of gas, air being 1.

For Natural Gas at High Pressure the formula generally accepted is that of T. R. Weymouth, $Q = 37\sqrt{\{(P_1^2 - P_2^2)\ d^{5.33}\}/L}$, where Q = quantity of gas, cu. ft. per hr.

reduced to standard conditions of 14.65 lb. absolute pressure and 60° F.; P_1 = absolute initial pressure, lb. per sq. in.; P_2 = absolute terminal pressure, lb. per sq. in.; d = inside diameter of pipe, in.; l = length of pipe, miles. This formula being for natural gas, the specific gravity has been assumed as 0.60 and merged into the coefficient 37.

Pole's formula translated into the form of the common formula for the flow of compressed air or steam in pipes, is $Q = c\sqrt{(p_1 - p_2)d^5/wL}$, in which Q = cu. ft. per min.; $(p_1 - p_2)$ = difference in pressure, lb. per sq. in.; w = density, lb. per cu. ft.; L = length, ft.; d = diameter, in. This gives 56.6 for the value of the coefficient c, which is nearly the same as that commonly used, *i.e.*, 60, in calculations of the flow of air in pipes.

An experiment made by Mr. Clegg, in London, with a 4-in. pipe, 6 miles long, pressure 3 in. of water, specific gravity of gas 0.398, gave a discharge into the atmosphere of 852 cu. ft. per hour, after a correction of 33 cu. ft. was made for leakage.

Substituting this value, 852 cu. ft., for Q in the formula $Q = C\sqrt{d^5h \div sl}$, we find C, the coefficient, = 997, which corresponds nearly with the formula given by Molesworth.

Wm. Cox (*Am. Mach.*, March 20, 1902) gives the following formula for flow of gas in long pipes:

$$\sqrt{\;(p_1^2 - p_2^2)/L.}$$

Q discharge, cu. ft. per hour at atmospheric pressure; d = diameter of pipe, in.; p_1 = initial and p_2 = terminal absolute pressure, lb. per sq. in.; l = length of pipe, ft.; L = length, miles. For $p_1^2 - p_2^2$ we may substitute the product $(p_1 + p_2) \times (p_1 - p_2)$. The specific gravity of the gas is assumed to be 0.65, air being 1. For fluids of any other specific gravity, s, multiply the coefficients 3000 or 41.3 by $\sqrt{0.65/s}$. For air, $s = 1$, the coefficients become 2419 and 33.3. J. E. Johnson, Jr.'s, formula for air, p. 1–14, translated into the same notation as Mr. Cox's, makes the coefficients 2449 and 33.5.

It is difficult to accurately check the tables, on account of the extra friction introduced by rough pipes, bends, etc. For bends, one rule is to allow $^1/_{42}$ of an inch pressure for each right-angle bend.

Another method of allowing for the effect of bends is to consider each one as equivalent to so many feet of pipe. The number of feet equivalent to one standard elbow, as given by J. M. Spitzglass, increases continuously from 1.7 ft. for 1-in. pipe to 49 ft. for 12-in. pipe.

The size to be selected for any particular service pipe often depends more upon other conditions than upon the rate at which gas is to be carried. For instance, in the United States, it is not considered good practice to lay any services for lamps with pipe less than 1 in. diameter, nor any house services with pipe of less than 1 $^1/_4$ in. to 1 $^1/_2$ in. diameter, although in the case of the lamp services a $^3/_8$-in. pipe, and in the case of the house services a 1-in. pipe would be sufficient to carry the gas without an undue loss in pressure.

Section 5
STEAM

TABLE OF CONTENTS

STEAM

Revised by A. G. Christie

1. PROPERTIES OF STEAM

The definitions on p. 3–79 for saturated heat of liquid, heat of vaporization, dry and saturated vapor, superheat, enthalpy, quality, etc., apply to water and steam.

The British Thermal Unit (B.t.u.) is defined on p. 3–72.

THE TEMPERATURE OF STEAM in contact with water depends upon the pressure under which it is generated. At the ordinary atmospheric pressure (14.7 lb. per sq. in.) its temperature is 212° F. As the pressure is increased, as when the steam is being generated in a closed vessel, its temperature, and that of the water in its presence, increases. See the Steam Tables pp. 5–04 to 5–11 for pressure-temperature relations.

THE ENTHALPY, formerly called the total heat in the steam tables is calculated above 32° F. and includes three elements: 1. The *total heat of saturated liquid* h_f, which is the heat required to raise the temperature of the water from 32° F. to the boiling temperature at the given constant pressure at which it boils. 2. The heat required to completely evaporate the water at that pressure and temperature. This heat is called the *internal latent heat* h_i. 3. The *external work* done by the steam in making room for itself against the pressure under which it is generated, APv_{fg}, where $A = 1/778.6$; P = absolute pressure, lb. per sq. ft.; v_{fg} = change in volume of vapor, cu. ft. per lb. The sum of the last two elements is the *latent heat* of steam h_{fg} or the *total heat of evaporation.* Thus the heat required to generate 1 lb. of steam at 212° F., from water at 32° F. and 14.696 lb. per sq. in. absolute pressure is:

Total heat of saturated liquid at 212° F., h_f	=	180 B.t.u.
Internal latent heat of steam, h_i	=	897.8
External work, $APv_{fg} = \{14.696 \times 144\,(26.82 - 0.017)\}/778.6$	=	72.4
Total heat of evaporation h_{fg}	=	970.2
Enthalpy or total heat of saturated vapor, h_g	=	1150.2 B.t.u.

The enthalpy or total heat of 1 lb. of wet steam at quality x is $h_x = h_f + xh_{fg}$.

The enthalpy or total heat of superheated steam is found by adding to the total heat of saturated vapor the energy added in the superheat. This is found by the calculus from

$h_s = \quad c_p dt = \bar{c}_p (T_2 - T_1)$, where h_s is the energy added; $\bar{c}_p$ = mean specific heat per lb. of superheated steam between T_1 and T_2 at constant pressure; T_1 = absolute temperature of evaporation corresponding to the given pressure and T_2 = absolute temperature of the superheated steam.

PROPERTIES OF SATURATED AND SUPERHEATED STEAM are given in Tables 1 and 2 which are condensed, by permission, from Keenan's Steam Tables and Mollier Diagram. See note on Tolerances, p. 5–07.

The Volumes of 1 lb. of saturated liquid, v_f, of the increase during evaporation v_{fg}, and of the saturated vapor v_g are given in Table 1 for steam at various pressures. To find the volume of 1 lb. of wet steam, $v_x = v_f + xv_{fg}$, where x is the quality. This formula must be used for pressures above 250 lb. per sq. in. v_f is relatively small as compared to v_g at low pressures and may be neglected in commercial calculations as, for instance, on exhaust steam volumes. Then $v_x{}^1 = xv_g$ is approximately correct.

The Volume of Superheated Steam is given in Table 2.

The Entropies of saturated liquid s_f, of evaporation s_{fg}, and of saturated vapor s_g, are given in Table 1. To find the entropy of 1 lb. of wet steam at x quality, $s_f + xs_{fg}$

The Entropies of Superheated Steam are given in Table 2.

The total heat of saturated liquid h_f as given in these tables does not include the work of the feed pump. It is the heat added to 1 lb. of water to raise it to the boiling point from 32° F., during which process the pressure remains constant and is that of evaporation.

Table 1.—Properties of Saturated Steam

Condensed by permission from Keenan's Steam Tables

Vacuum, in. of Mercury	Absolute Pressure, lb. per sq. in. p	Temp., deg. F. t	Specific Volume, cu. ft. per lb. Of Liquid v_f	Specific Volume, cu. ft. per lb. Of Steam v_g	Weight of Steam, lb. per cu. ft.	Enthalpy or Heat Content, B.t.u. per lb. In Liquid h_f	Enthalpy or Heat Content, B.t.u. per lb. Latent h_{fg}	Enthalpy or Heat Content, B.t.u. per lb. Total h_g	Entropy Of Liquid s_f	Entropy Of Vaporization, s_{fg}	Entropy Of Steam s_g

STEAM TABLE TOLERANCES AND CORRECTIONS.—The Third International Steam Table Conference has adopted tolerances for steam tables (*Mech. Engg.*, Nov., 1935) which have been made possible by greater refinements in research. Tables 4, 5, and 6 are the skeleton tables issued by the conference. Table 3 gives corrections which may be applied to Tables 1 and 2 to bring them into conformity with the International tolerances. Table 3 was compiled from curves developed by Ernest L. Robinson of the General

(*Continued on p. 5–13*)

Table 2.—Properties of Superheated Steam

v = specific volume, cu. ft. per lb.; h = enthalpy or total heat content, B.t.u. per lb.; s = entropy, B.t.u. per deg. F. per lb.

Absolute Pressure, lb. per sq. in.	Temperature, Sat., deg. F.		Superheated Steam, Total Temperature, deg. F.

Table 3.—Steam Table Corrections.

The values ΔH (enthalpy) and ΔN (entropy) are to be *deducted* from the values given in Tables 2 and 3, to make them conform to the International Steam Table Conference tolerances.

Pressure, lb. per sq. in.	Steam Temperature, deg. F.									
	800		850		900		950		1000

Observed values of critical temperature: Mass. Inst. of Tech., 374.11° C.; Reichsanstalt, 374.2±0.1°C.

* By definition.

Table 5.—Specific Volume of Compressed Liquid Water and Superheated Steam.

(Third International Steam Table Conference, 1934)

Values to left and below the heavy line are for compressed liquid water; values to the right and above it are for superheated steam. Of each pair of figures the upper represents the accepted value and the lower the tolerance (±)

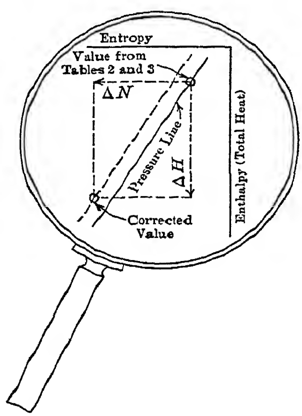
Electric Co., who based them on values of enthalpy (total heat) and entropy of saturated vapor furnished by N. S. Osborne of the U. S. Bureau of Standards, which conform to the International tolerances, and on values of enthalpy of superheated steam contained in Table 6.

Some of the values of enthalpy and entropy as given in Tables 1 and 2 are higher than are permitted by the conference tolerances. The corrections ΔH (enthalpy) and ΔN (entropy) as given in Table 3 should be *deducted* from the values in Tables 1 and 2, to bring them into conformity with the International tolerances. Fig. 1 shows the application of the corrections to the Mollier diagram.



. 1. Application of Correction to Mollier Diagram

HEAT ADDED BY THE BOILER-FEED PUMP.—Feedwater at a pressure and temperature much below that in the boiler frequently is delivered to the boiler-feed pump and raised to boiler pressure. The work per lb. of water done by the feed pump, $W_f = v_s(P_b - P_s)/778.6$ B.t.u., where P_b = boiler pressure, lb. per sq. ft.; P_s = absolute pump suction pressure in lb. per sq. ft.; v_s = volume, cu. ft., of 1 lb. water at the temperature of suction. This formula assumes that water is incompressible, which is approximately correct for usual pressure ranges. The work of the boiler-feed pump is of a small order at pressures below 350 lb. per sq. in., but is significant at high boiler pressures. For example, let water enter the feed pump at 220° F. and 20 lb. per sq. in., abs.; the work of the feed pump lifting 1 lb. of water under these conditions to boiler pressure is given in Table 7.

TEMPERATURE-ENTROPY DIAGRAM OF WATER AND STEAM.—Changes taking place in steam expansions or compressions may conveniently be represented on a temperature-entropy diagram. The line OA, Fig. 2, is the origin, *i.e.*, 32° F., from which entropy is measured on horizontal lines, and the line OS is the line of zero temperature, absolute. The diagram represents the changes in the state of 1 lb. of water due to the addition or subtraction of heat or to changes in temperature. Any point on the diagram is called a *state-point*. A is the state of 1 lb. of water at 32° F. or 491.6° abs., B the state at 212° F., and C at 392° F., corresponding to about 226 lb. per sq. in. absolute pressure. K is the state point at the critical temperature 706.1° F. At 212° F. the area $OABb$ is the heat added to the water, and Ob is the increase of entropy. At 392° F., $bBCc$ is the further addition of heat to the water, and the entropy at C, measured from OA, is Oc. The two quantities added are nearly the same, but the second increase of entropy is the smaller, since the mean temperature at which it is added is higher. If Q = the quantity of heat added, and T_1 and T_2 are, respectively, the lower and the higher temperatures, the addition of entropy from 32° F. to 212° F., $s_f = \bar{c}_p \log_e (T_2/T_1) = 0.3119 = Ob$, where $\bar{c}_p$ is the mean specific heat of water over this temperature range. Accurate values of the entropy of water, taking into account the variation in specific heat, will be found in the Steam Tables.

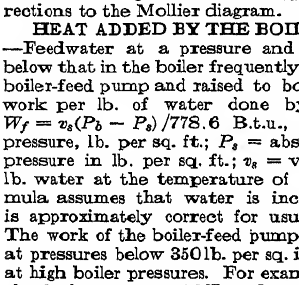


Fig. 2. Temperature-Entropy Diagram

Let the 1 lb. of water at the state B have heat added to it at the constant temperature of 212° F. until it is evaporated. The quantity of heat added will be the latent heat of

Table 7.—Work of Boiler-Feed Pump Lifting 1 Lb. of Water to Boiler Pressure.
Water enters pump at 220° F. and 20 lb. per sq. in., abs.

Absolute Boiler Pressure, lb. per sq. in.	Work, B.t.u. per lb.	Absolute Boiler Pressure, lb. per sq. in.	Work, B.t.u. per lb.	Absolute Boiler Pressure, lb. per sq. in.	Work, B.t.u. per lb.
40	0.061	750	2.25	3000	9.20
250	.710	1500	4.57	4000	12.29
450	1.328	2000	6.12	6000	18.47

evaporation at 212° (see Steam Table) or h_{fg} = 970.2 B.t.u., and it will be represented on the diagram by the rectangle *bBFf*. Dividing by T_1 = 671.6, the absolute temperature, gives s_{fg} = 1.4446 = *BF*. Adding s_f = 0.3119 gives s_g = 1.7564, the entropy of 1 lb. of steam at 212° F. measured from water at 32° F. = *Of*.

In like manner if we take h_{fg} = 833.0 for steam at 392° F., s_{fg} = 0.9782 = *CE*, and s_f = entropy of water at 392° F. = 0.5567, = *Oc*, the sum s_g = 1.5349 = *Oe*.

E is the state point of dry saturated steam at 392° F. and *F* is the state point at 212° F. The line *EFG* is the *line of saturated steam* and the line *ABC* the *water line*. The line *CE* represents the increase of entropy in the evaporation of water at 392° F. If entropy *CD* only is added, or *cCDd* of heat, then a part of the water will remain unevaporated, *viz.*, the fraction *DE/CE* of 1 lb. The state-point *D* thus represents wet steam having a dryness fraction of *CD/CE*.

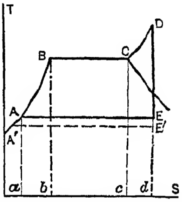

Fig. 3. Rankine Cycle

K is the *critical state for water* at a temperature of 706.1° F. and a pressure of 3226 lb. per sq. in., abs. To the left of *K* the substance is water; above *K* to the right, it becomes superheated steam. At pressures above 3226 lb. per sq. in., abs., the water has no latent heat but passes directly to superheated steam as at *K*. Line *AL* represents (but not to scale) the states for a pressure of 6000 lb. per sq. in., abs.

If steam having a state point *E* is expanded adiabatically at constant entropy to 212° F. its state-point is then e_1, having the same entropy as at *E*, a total heat less by the amount represented by the area $BCEe_1$, and a dryness fraction Be_1/BF. If it is expanded while remaining saturated, heat must be added equal to *eEFf*, and the entropy increases by *ef*.

If heat is added to the steam at *E*, the temperature and the entropy both increase, the line *EH* representing the *superheating*, and the area *EHhe* is the heat added. If from the state point *H* the steam is expanded adiabatically at constant entropy, the state-point follows the line *HJ* until it cuts the line *EFG*, when the steam is dry saturated, and if it crosses this line the steam becomes wet.

If the state-point follows a horizontal line to the left of line *EFG*, and to the water line *ABC* it respresents *condensation at a constant temperature*, the amount of heat rejected being shown by the area under the horizontal line down to line, *Og*. If heat is rejected at a decreasing temperature, corresponding with the decreasing pressure at release in a steam engine, or condensation in a cylinder at a decreasing pressure, the state-point follows a curved line to the left, as shown in the dotted curved line on the diagram.

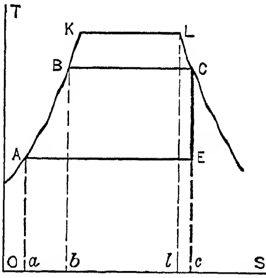

Fig. 4. Effect of Increased Pressure

In practical calculations with the entropy-temperature diagram it is necessary to have at hand tables or charts of entropy, enthalpy or total heat, etc., such as are given in Keenan's Steam Tables and Mollier Diagram, Goodenough's Properties of Steam and Ammonia, Marks and Davis's Steam Tables, and other works.

REVERSIBLE ADIABATIC EXPANSION on the temperature-entropy diagram is a vertical line at constant entropy. When it is necessary to make exact calculations of the conditions at the end of such expansion this can be done by means of the entropies. Let state 1 be the initial condition and state 2 the final condition after adiabatic expansion. With wet steam $s_{f_1} + x_1 s_{fg1} = s_{f2} + x_2 s_{fg2}$ from which x_2 can be found and the enthalpy or total heat at state 2 calculated from $h_2 = h_{f2} + x_2 h_{fg2}$. The heat drop, ($h_1$ —) then can be found. With superheated steam expanding into the wet region $s_1 = s_{f2} + x_2 s_{fg2}$. Then x_2 can be found and h_2 calculated as above.

STEAM CYCLES.—As stated on p. 3–78 the ideal cycle for a heat engine is the Carnot cycle, which is represented by a rectangle on the temperature-entropy diagram.

The Rankine or Clausius Cycle is shown in Fig. 3. The feedwater enters at temperature *A* and has the quantity of heat *ABba* added to it at constant pressure, increasing its temperature to the boiling point *B*. Then the latent heat *BCcb* may be added and finally the superheat *CDdc*. The steam expands adiabatically in an ideal engine along the line of constant entropy *DE* and exhausts to a condenser discharging the heat *EdaA* to the cooling water. The heat available for work is represented by the area *ABCDEA*

The efficiency of the cycle is the ratio of the heat available for work to the heat supplied, *i.e.*, area *ABCDEA/ABCDda*. This cycle is the usual standard of comparison for straight expansion steam engines and turbines.

The efficiency of the Rankine cycle can be increased by increasing the heat available for work in a greater ratio than the increase of heat supplied. This may be done by lowering the exhaust temperature. Obviously from Fig. 3, when the exhaust temperature is lowered to *A'E'*, less heat is rejected to the condenser and more heat is available for work. Hence when low absolute pressure or vacuum can be utilized it is desirable to lower the vacuum temperature as close as possible to that of the coldest available cooling water. If the pressure is increased without superheat, it would appear from Fig. 4 that efficiency increases as the pressure rises from *BC* to *KL*. Emswiler points out that the enthalpy or total heat of saturated steam increases up to 400 lb. per sq. in., abs., as shown in the steam tables and then decreases to a minimum at the critical pressure of 3226 lb. per sq. in., abs. The thermal efficiency of the Rankine cycle increases to a maximum with saturated steam at 2000 lb. per sq. in., abs., and then decreases slightly. But increased pressure leads to lower quality steam at the lower stages of expansion, and in turbines this causes internal losses which offset the gain by very high initial pressures.

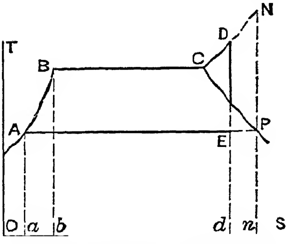

Fig. 5. Effect of Increased Steam Temperature

Increased steam temperature at moderate pressure as shown by Fig. 5 by the Rankine cycle *ABCNPA*, gives only a small increase in thermal efficiency. In turbines, such an increase in temperature leads to a substantial increase in efficiency, as less of the expansion takes place in the saturated section and this leads to a decrease in internal losses in the turbine. Obviously an increase in both pressure and superheat would tend to increase cycle efficiency.

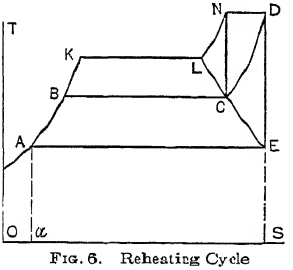

Fig. 6. Reheating Cycle

Reheating Cycle.—The use of high pressures with moderate superheat leads to high internal losses in a turbine. This is overcome by *resuperheating* as shown in Fig. 6 where pressure is increased from *BC* to *KL* but superheat temperature remains constant at *ND*. The steam after expansion from *N* to *C* is resuperheated again to the original temperature *D* and expanded to *E*. This is known as the *Reheating Cycle*. The theoretical advantages, as measured by cycle efficiencies, are small, but the practical gains due to decreased internal losses in steam turbines and engines are considerable.

Extraction or Regenerative Cycle.—Regenerative heating of the feedwater is another method of improving cycle efficiency. In Fig. 7 assume that at every infinitesimal step in expansion there is a small portion of steam withdrawn from the cycle to preheat the feed. The expansion line *CR* represents this condition. *CR* is parallel to *AB* for the heat added to the feed *CRrc* must equal *ABba*. But by geometry *ABCR* equals *BCEP*, which would be the energy available for work in a Carnot cycle. Also the heat supplied *ABCRra* equals *BCcb*. Hence theoretically with saturated steam the *regenerative cycle* can equal the maximum ideal efficiency of any engine, that is, of the Carnot cycle between the temperature limits. With superheat, the regenerative cycle is theoretically not so efficient, as it cannot utilize all heat at the highest temperature. This easily applied and efficient cycle should be used in every steam turbine power plant.

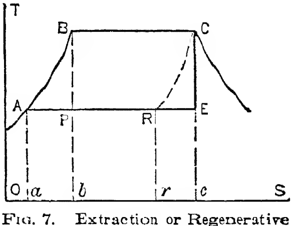

Fig. 7. Extraction or Regenerative Cycle

Many stations now operate on a combination of these last two cycles known as the *regenerative-reheating cycle*. Both extraction feed heating and interstage reheating are employed.

BINARY-VAPOR CYCLES.—The critical pressure of steam is 3226 lb. per sq. in., abs., with a temperature of 706.1° F. Several attempts have been made to use a fluid with higher range boiling points superimposed upon the regular steam cycle forming a *Binary-*

vapor cycle. The employment of the mercury vapor–steam cycle provides one of the most efficient means of generating power from the combustion of fuels.

Mercury-vapor-Steam Cycle.—Fig. 8 illustrates the mercury-vapor–steam cycle on a temperature-entropy diagram. The mercury vapor boils with 165 lb. per sq. in. gage pressure at 999.6° F., and is expanded isentropically to 28 in. vacuum. In practice this would be done in a mercury turbine and useful work developed. The mercury condenses at 28 in. vacuum at 456.8° F. in a condenser-steam boiler which transfers the exhaust heat from the mercury to the steam. The saturated steam is generated at 360 lb. per sq. in., gage, 438.5° F., by the condensation of the mercury vapor. For its efficient use in the steam turbine, the steam is superheated by flue gases from the mercury boiler to 700° F. and expanded to 29 in. vacuum, using regenerative extraction for feedwater heating. On account of the low heat values per pound of mercury, it is necessary to use about 10 lb. of mercury per 1 lb. of steam in the mercury vapor-steam cycle. With isentropic

Table 8.—Properties of Saturated Mercury Vapor*

For calculations involving superheated mercury vapor, the mean specific heat at constant pressure, c_p, may be taken as 0.0248.

* Abstracted from Properties of Mercury Vapor, by Lucian A. Sheldon, General Electric Company, 1927.

expansion of both mercury vapor and steam, and with extraction feed heating in the cycles shown in Fig. 8, an efficiency of 58.8% may be obtained. The maximum possible Carnot cycle efficiency between the temperature limits of 999.6° F. and 79° F. is 63.4%. Higher efficiencies can be developed on this combined cycle than on any of the preceding cycles.

The properties of mercury vapor are given in Table 8.

Diphenyl and Diphenyl-oxide Cycles.— Certain organic substances such as diphenyl and diphenyl-oxide have been proposed for binary cycles besides mercury. Diphenyl-oxide with additions of naphthalene to regulate the melting point is sold commercially as Dowtherm by the Dow Chemical Co., Midland, Mich. The naphthalene appears to have little effect on the thermal properties of the mixture beyond altering the point of solidification. Table 9 gives certain of the thermal properties of diphenyl-oxide. Above 750° F. diphenyl-oxide slowly decomposes to other organic compounds. Diphenyl has somewhat lower boiling temperature than diphenyl-oxide and also a slightly lower enthalpy or total heat per lb. for the same absolute pressures, although the critical temperature is somewhat higher.

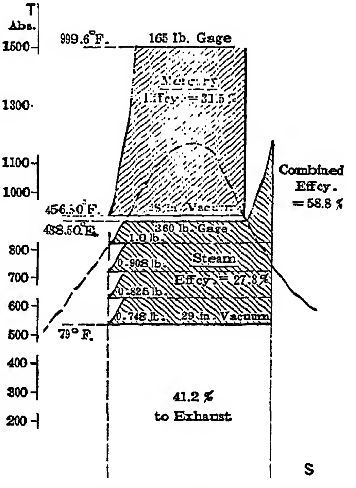

FIG. 8. Temperature-Entropy Diagram of a Mercury-vapor-Steam Cycle

SUPERSATURATED STEAM. (Ewing's Thermodynamics for Engineers.) — Callendar has shown that the adiabatic expansion of superheated steam follows closely the equation $P(V - b)^{1.3} = constant$, where P = pressure, lb. per sq. ft., abs.; V = specific volume, cu. ft. per lb. at pressure P; b = volume of 1 lb. of water at 32° F., *i.e.*, 0.017 cu. ft. Ordinarily b may be neglected without serious error, except at high pressures.

The usual theory of heat assumes that isentropic expansion of saturated steam takes place in thermal equilibrium, *i.e.*, condensation proceeds in the wet region as indicated on a Mollier diagram when expansion takes place at constant entropy. But such condensation takes considerable time, for droplets must form and grow in the mass of the steam. Consequently, sudden expansion of a saturated vapor may produce a temporary condition in which the mass continues to expand as superheated steam without any condensation taking place. This condition is called *supersaturation*. The density of the vapor in this state is abnormal, and higher than the density of saturated vapor at the actual pressure. The temperature at the end of expansion is lower than the temperature of saturation at that pressure and the vapor is said to be under-cooled. The supersaturated condition is not stable and disappears through condensation of part of the vapor. The temperature of the remaining mass is raised by the latent heat given off

Table 9.—Properties of Saturated Diphenyl-oxide Vapors

950	Critical temperature						

during condensation until thermal equilibrium is restored. Supersaturation, therefore, may be assumed to occur when steam is expanded through a nozzle or orifice and the saturation line is passed during expansion. Such expansion can be represented by the equation $P(V - b)^{1.3} = constant$ as in the case of superheated steam.

Effect of Supersaturation.—The primary effect of supersaturation in nozzles is to increase the discharge of saturated steam by about 5% for a given throat area as compared with that usually calculated for saturated steam (see Callendar's Steady Flow of Steam through a Nozzle or Throttle, Inst. M. E., 1915). The secondary effect is to cause an increase of entropy and volume after passing the throat when the steam in the nozzle becomes wet. Applying the supersaturation theory, the critical pressure in the throat of a nozzle becomes $0.5457P_1$, and the flow of steam through any nozzle becomes $W = 0.3155A\sqrt{P_1/V_1}$, where W = lb. of steam per sec.; A = throat area, sq. in.; P_1 = initial pressure lb. per sq. in., abs., and V_1 = specific volume, cu. ft. per lb., at initial condition at pressure P_1. Since condensation requires time, it is doubtful if any takes place up to the nozzle throat, or if equilibrium is fully restored by the time the steam leaves the nozzle. Martin (A New Theory of the Steam Turbine, *Engg.*, vol. cvi, 1918) holds to the view that the steam is never in thermal equilibrium in a steam turbine until the condenser is reached, and he has worked out a new analysis of steam turbine performance on this basis. He also presents a new steam chart with lines representing supersaturated conditions. It also can be shown that there is about 6% less heat available to do work from that portion of the expansion below the saturation line when expansion is assumed to continue in the adiabatic supersaturated condition at constant entropy than if it took place in thermal equilibrium. This decrease in available energy usually is not considered in steam turbine design, but may be a factor in causing the lowered stage efficiencies experienced with saturated steam. For further information, see Callendar's Properties of Steam, Ewing's Thermodynamics for Engineers, Stodola's Steam Turbines, Goudie's Steam Turbines, and Martin's paper referred to above. See also Martin's later paper, The Proportioning of Steam Turbine Blading, *Engg.*, Jan. 6, 13, 20, 27, and Feb. 3, 1922; The Supersaturation Limit, *Engg.*, May 18, 1923; Powell, Supersaturation of Steam and its Influence on Some Problems of Steam Engineering, *Engg.*, June 7, 21, 1929; Yellot, Supersaturated Steam, *Trans.* A.S.M.E., FSP–56–7, 1934.

2. THE MOLLIER DIAGRAM (Keenan's)

CONSTRUCTION.—(See Fig. 9.) The enthalpy or total heat of 1 pound of steam above 32° F. is plotted as ordinates, and entropies above 32° F. form abscissae. Lines of constant absolute pressure in lb. per sq. in. slope up from left to right. In the low-pressure region at the right-hand side, dotted lines represent absolute pressures in inches of mercury, and are found convenient for exhaust steam calculations. Below the saturation line, curves of constant moisture content, in percent, slope down from left to right. Above the saturation line are shown lines of constant temperature and lines of constant superheat, both in deg. F. Heat quantities may be found directly from the diagram. For instance, the enthalpy or total heat at 650 lb. per sq. in. absolute, 860° F. from the chart = 1442 B.t.u. at entropy 1.6536. Again the total heat at 1 in. of mercury absolute and 89% quality (11% moisture) = 979.5 B.t.u.

NOTE.—A Mollier diagram about 20″ × 32″ accompanies Keenan's Steam Tables. Extra copies can be procured from the American Society of Mechanical Engineers.

THROTTLING EFFECTS.—In the phenomena of throttling or wire-drawing the enthalpy or total heat per lb. of steam is the same in the final as in the initial state, providing no energy has gone to increase velocity and no heat is lost by radiation. A line of constant total heat represents throttling on the Mollier diagram. Thus, if steam at 650 lb. per sq. in., abs., 860° F., is throttled by the turbine governor to 400 lb. per sq. in., abs., its condition on the constant total heat line for 1442 B.t.u. at 400 lb. per sq. in., abs., is 845° F.

The *quality* of slightly wet steam can be readily determined on the Mollier diagram from throttling calorimeter readings. Given: steam line pressure, 125 lb. per sq. in., gage (140 lb. per sq. in., absolute); atmospheric pressure, 14.696 lb. per sq. in., abs., in the calorimeter; temperature in the calorimeter, 280° F. From the chart, enthalpy or total heat in calorimeter at 14.696 lb. per sq. in., abs., and 280° F. = 1182.7 B.t.u., which total heat line representing throttling intersects the 140-lb. absolute pressure line at 1.1% moisture, giving 98.9% quality.

The heat available on the *Rankine cycle* or *heat drop* results from isentropic expansion, which follows a line of constant entropy. Thus, a turbine receives steam at 450 lb. per sq. in., abs., 750° F., and exhausts at 29 in. vacuum. Total heat at 450 lb., abs., 750° F., h_1 = 1387.8 B.t.u.; s = 1.6488. At 1 in. abs., s = 1.6488, h_2 = 885.5 B.t.u. Heat avail-

able on the Rankine cycle or the heat drop, $(h_1 - h_2) = 1387.8 - 885.5 = 502.3$ B.t.u. per lb. of steam.

Heat Added as Reheat in a reheating turbine also is readily found. Thus steam leaves the high-pressure section of the unit at 120 lb. per sq. in., abs., 370° F., and is reheated with a 10 lb. per sq. in. pressure drop in the reheater to 700° F. Total heat at

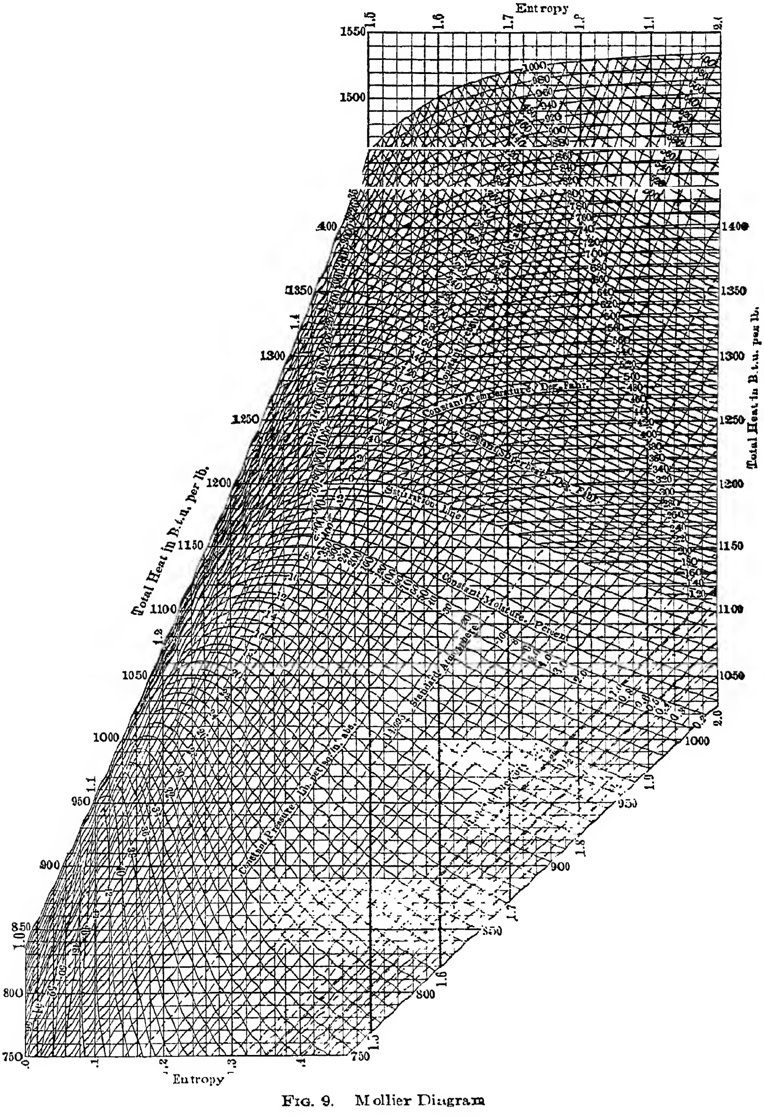

FIG. 9. Mollier Diagram

120 lb., abs., 370° F., = 1207.0 B.t.u. Total heat at 110 lb., abs., 700° F., = 1377.7 B.t.u. Heat added by reheater = 1377.7 − 1207.0 = 170.7 B.t.u. per lb.

The Condition of the Exhaust Steam can be found quickly on a Mollier diagram. In the case of a steam engine, the heat per pound to exhaust

$$h_e = (1 - L)h_1 - (\text{I.Hp.} \times 2543/W),$$

where h_1 = total heat per pound at throttle; L = external heat losses, as radiation, piston- and valve-rod leakage and conduction, etc., expressed as a decimal of the initial total heat; I.Hp. = indicated horsepower; W = total steam per hour, lb. L may be assumed as 0.01 for reciprocating engines. When h_e is determined, the quality can be found by locating the intersection of the total heat line for h_e and the absolute exhaust pressure line.

3. FLOW OF STEAM IN PIPES *

Formulas in general use, expressing the pressure drop along a pipe in which a fluid is flowing, are mainly empirical. They refer to a particular fluid, and do not take into account the surface condition of the pipe interior. Examples of such empirical formulas (see earlier editions of this book) are those of Babcock, Fritzsche, Unwin, Broido and others for steam; Hazen and Williams for water; and Unwin, Taylor and others for air.

The general formula for pressure drop in isothermal turbulent flow is

$$\Delta p = f(L/D)(\rho v^2/2g), \qquad [1]$$

where Δp = pressure drop; f = friction factor; L = length of pipe; D = diameter of pipe; ρ = density of the fluid; v = velocity of the fluid; g = acceleration due to gravity, all expressed in a homogeneous system of units.

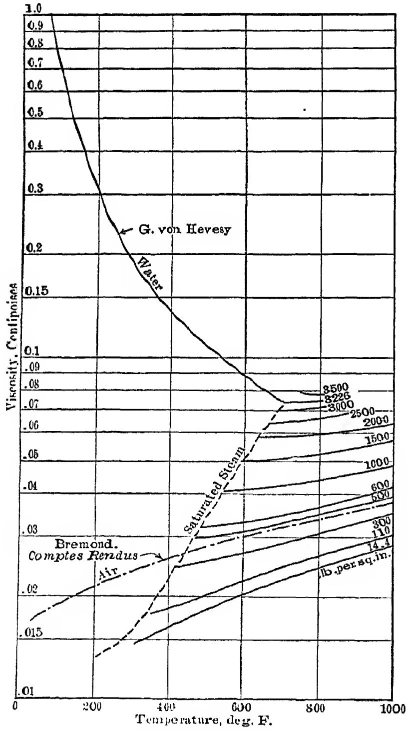

Fig. 10. Viscosity of Steam and Water

In some of the empirical formulas, as, for example, Babcock's for steam and Unwin's for air, it is recognized that f varies with the diameter of the pipe, both containing the term $\{1 + (3.6/d)\}$, in which d is the diameter of the pipe in inches. Still others recognize the effect of velocity, as Fritzsche's formula for friction factor, which contains the term $w^{-1/7}$, in which w denotes the weight flowing per second. The difficulty in using empirical formulas lies in the limitations of application, any change of fluid requiring a modification of the friction factor.

A rational method based on dimensional analysis (see Eshbach, Handbook of Engineering Fundamentals, Section 3, Vol. 1 of this series) has shown the friction factor to be a function of the density, velocity and viscosity of the fluid, as well as the diameter of the pipe. Therefore, a plot of friction factor against Reynolds number $\rho v d/\mu$ is applicable to any fluid, since all the physical properties affecting flow have been taken into account. μ = viscosity. However, the condition of the interior surface of the flow channel also has an effect on the friction factor as does the type of flow, whether viscous or turbulent.

A comprehensive study and correlation of all the available test data were undertaken by Mr. R. J. S. Pigott (*Mech. Engg.*, Aug., 1933). The fluids were brine, water, oil, air, steam and gas, and the pipe materials were glass, lead, tin, brass, steel (plain and riveted), and cast iron (plain and tarred). The results of the study are given on p. 4–59, and are

* Contributed by Robert K. Behr.

recommended for general use in the solution of flow problems. The type of flow may be viscous or turbulent, and the nature of the fluid flowing is immaterial, since its characteristics are taken into consideration in the solution of the problem.

The procedure is as follows: From Table 16, p. 4–60, select the curve to be followed by means of the pipe material and the internal diameter in inches. Solve for the Reynolds number. See p. 4–57. Enter Fig. 4, p. 4–60, or Fig. 11, below with Reynolds number; proceed vertically to the curve selected, and the ordinate is the friction factor.

The Reynolds number $\rho VD/\mu$ is a pure number, dimensionless, and, therefore, can be obtained in any system of consistent units. If the ft.-lb.-sec. system is used, the formulas for pressure drop in turbulent flow are:

Circular pipes
$$\left\{\begin{array}{l}\Delta p = 0.000108\, f(L/D)\rho v^2 \text{ lb. per sq. in.} \qquad [2]\\ \Delta p = 0.001295\, f(L/d)\rho v^2 \text{ lb. per per sq. in.} \qquad [3]\end{array}\right.$$

Any shape
$$\Delta p = 0.000027\, f(L/M)\rho v^2 \text{ lb. per sq. in.} \qquad [4]$$

where Δp = pressure drop, lb. per sq. in.; f = friction factor, a number; L = length of pipe, ft.; ρ = density of fluid, lb. per cu. ft.; v = mean velocity, ft. per sec.; D = internal diameter, ft.; d = internal diameter, in.; M = mean hydraulic radius, ft.; μ = absolute viscosity, lb. per ft. sec.

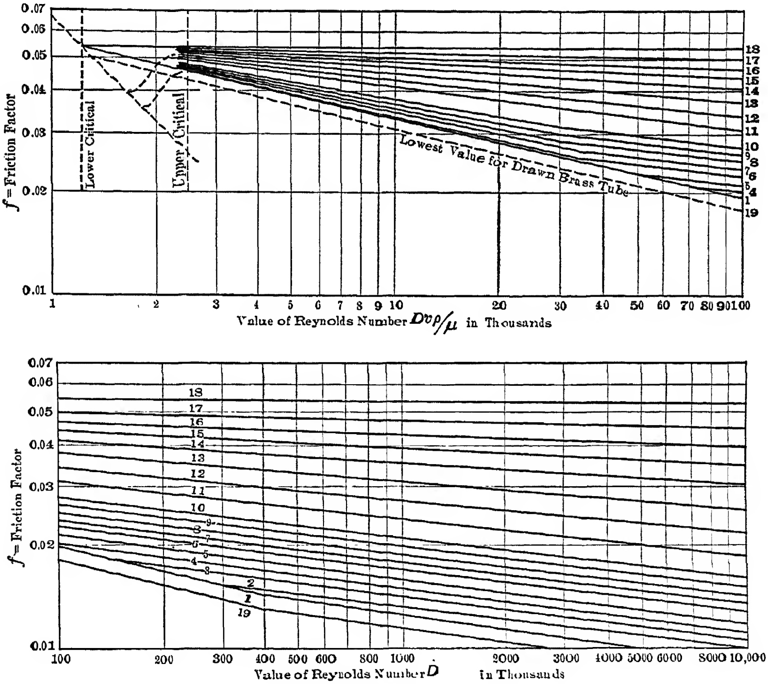

FIG. 11. Friction Factors and Reynolds Numbers

Usual velocities of steam in pipe lines are (S. Crocker, *Power*, June 6, 1926): Saturated steam, 0 to 15 lb. per sq. in. gage pressure, for heating service, 4000–6000 ft. per min.; saturated steam, 50 lb. per sq. in. gage pressure, and over, for miscellaneous services, 6000-8000 ft. per min.; superheated steam, 200 lb. per sq. in. gage pressure and over, for large turbines and boiler lines, 10,000–15,000 ft. per min.

Although the above formulas are of the turbulent form, they are applicable to either

type of flow, so long as the friction factor is selected from the chart according to the Reynolds number.

For viscosity of steam and water, see Fig. 10 (Viscosity of Water and Superheated Steam, Hawkins, Solberg and Potter, *Trans.* A.S.M.E. FSP–57–11, 1935), to which has been added the viscosity of air according to Bremond, *Comptes Rendus*. To convert viscosity in centipoises to ft.-lb.-sec. units, multiply by 0.000672.

The density of water and steam can be obtained from the steam tables, pp. 5–04 to 5–09, and the density of air from the base value, 0.0807 lb. per cu. ft. at 32 deg. F. and 29.92 in. of mercury, corrected for temperature and pressure by the perfect gas law (see p. 3–74).

RESISTANCE TO FLOW BY BENDS, VALVES, ETC.—Unfortunately no data on the resistance of specials have been assembled on the same basis as given above for straight pipe. One method in vogue is known as the velocity head method, the loss for each type of fitting being given as a number of velocity heads. The method of expressing the loss due to pipe fittings and valves, as the equivalent resistance of so many feet of straight pipe is convenient and time-saving in that one calculation will suffice, the length of straight pipe being adjusted to include the bends, valves, etc. Dean E. Foster (*Trans.* A.S.M.E. xlii, p. 648, 1920) gives formulas for the length of straight pipe equivalent in resistance to screwed fittings, as follows:

For steam, air and gases, $L_e = 43.7\, r_f\, D^{1.2}$ . . . . [5]

For water, $L_e = 53.75\, r_f\, D^{1.25}$ . . . . [6]

where L_e = length, ft., of straight pipe of resistance equivalent to the fitting; D = inside diameter of pipe, ft.; r_f = resistance factor of the fitting, which is dependent upon the type of fitting. Table 10 has been computed from formulas [5] and [6] for standard pipe.

Table 10.—Resistance of Screwed Pipe Fittings *

* For flanged fittings use 0.75 × resistance of screw fittings.

The weight of steam flowing through a pipe can be directly related to the value of Δp by rearranging equation [3] in terms of weight and area. The weight of steam flowing in lb. per sec. $= w = Av\rho$, where A = area of pipe, sq. ft., and v = velocity, ft. per sec. $A = \pi D^2/4 = \pi(d/12)^2/4$, whence $v = w/\{\rho\pi(d/12)^2/4\}$. By substituting this value of v in equation [3], we derive the equation

$$w = \sqrt{\Delta p\rho d^5/43.53 fL} \quad [7]$$

EXAMPLE.—Required the size of pipe to deliver 375,000 lb. of steam per hour, through a main 150 ft. long, having 2 gate valves, 1 angle valve and 3 long-radius ells, with fusion welded flanges. Average steam pressure in the main, 500 lb. per sq. in., abs.; steam temperature 800° F.; pressure drop, Δp, not to exceed 10 lb. per sq. in. *Solution.*—Assume a velocity of 12,500 ft. per min. = 208.34 ft. per sec. From Table 2, p. 5–09, density of steam at 500 lb. per sq. in., abs. pressure, and 800° F. temperature $= \rho = 1/v = 0.69614$.

$$\text{Area of pipe required} = (375{,}000 \times 144)/(60 \times 0.69614 \times 12{,}500) = 103.43 \text{ sq. in.}$$

From Table 13, the allowable fiber stress in electric fusion-welded Grade C steel pipe is 7200 lb. per sq. in., giving a value of schedule number for Table 14 of $1000 \times 500/7200 = 69.4$. Interpolating in Table 14, select a 12-in. O.D. pipe with wall thickness of 0.625 in. Then $d = 11.5$ and $D = 0.958$. From Fig. 10, find $\mu = 0.0345$; converting to the ft.-lb. sec. system,

$$\mu = 0.0345 \times 0.000672 = 0.0000232.$$

Reynolds number $= \rho vD/\mu = 0.69614 \times 208.34 \times 0.958/0.0000232 = 5{,}989{,}000$. Table 16, p. 4–60, indicates that f is determined by curve 4, Fig. 11, whence $f = 0.0119$.

By equation [5] and a value of f from Table 10, the equivalent length of straight pipe for 2 gate valves with flanged joints will be: $2 \times 0.75 \times 43.7 \times 0.25 \times 0.958 = 15.55$ ft. Similarly, the equivalent lengths of straight pipe for 1 angle valve and 3 long-radius ells will be, respectively, 29.50 ft. and 30.81 ft. Total equivalent length of straight pipe then will be $150 + 15.55 + 29.50 + 30.81 = 225.86$ ft. By equation [3] $\Delta p = 0.001295 \times 0.0119 \times (225.86/11.5) \times 0.69614 \times 208.34^2 = 9.15$ lb. per sq. in. Should the calculation of Δp result in too large a value, the calculation should be repeated with a larger diameter of pipe.

4. STEAM PIPING *

The construction of steam and other pressure piping is covered by the Code for Pressure Piping, American Tentative Standard, 1933. The code covers steam, gas, air, oil, and district heating piping systems, and fabrication details of hangers, supports, pipe joints, and expansion of pipes. The following notes are abstracted from the code.

Pipe

Steam piping systems are classified in the code according to service, gage pressures and temperatures as follows: 1. Pressures 250–1500 lb. per sq. in.; temperatures 450–750° F. 2. Pressures 125–250 lb. per sq. in.; maximum temperature, 450° F. 3. Pressures 25–125 lb. per sq. in.; maximum temperature 450° F. 4. Pressures under 25 lb. per sq. in.; maximum temperature, 450° F.

MATERIAL that may be used for pipe for these various services is given in Table 11. Chemical and physical properties of the various materials are summarized in Table 12.

THICKNESS OF PIPING.—For inspection purposes, minimum thickness of pipe wall is

$$t_m = (PD/2S) + C \quad [8]$$

where t_m = minimum pipe wall thickness, in.; P = maximum internal service pressure, lb. per sq. in., gage; D = actual outside diameter of pipe, in.; S = allowable stress in material, lb. per sq. in., plus water hammer allowance in case of cast-iron pipe; C = allowance for threading, mechanical strength and corrosion, in.; Values of S for various temperatures and materials are given in Table 13. Values of C are: Cast-iron pipe, cast in horizontal molds or centrifugally, 0.14; cast-iron pipe, pit-cast, 0.18; threaded steel, $0.8/n$, where n = no. of threads per in.; grooved steel pipe, depth of groove, in.; plain end steel, wrought-iron or non-ferrous pipe or tube, 1 in. size or smaller, 0.05; over 1 in. size, 0.065. Plain end pipe includes pipe joined by flared compression couplings, by lap (Van Stone) joints, and by welding.

Tables 14 and 15 (A.S.A.B–36) show approximately the thickness of steel and wrought-iron pipe to be used for various pressure-stress relations, but exact thickness should be calculated according to the Code rules.

Water hammer allowance for cast-iron pipe to be added to P in formula [8] is

Pipe size, in.	4–10	12–18	20	24–30	36–48	54–84
Water hammer allowance lb. per sq. in.	120	110	100	95	90	85

Valves and Fittings

Fittings shall conform to the requirements of the several classes of service as listed below. Welded fittings may be used. Wrought or forged fittings for welding, and built-up manifolds, shall conform to the same thickness requirements and be constructed like the pipe with which they are to be used.

Valves shall be manufacturers' standard for the respective pressure and temperature, and conform to the requirements for the several classes of service as listed below.

* Staff contribution.

Steam Pressures 250–1500 lb. per sq. in., gage. Temperature, 450–1500° F.—Flanged openings or welding ends are required on all valves and fittings above the following pipe sizes in the given pressure ranges:

Pipe size, in....................	3	2	1 1/2
Pressure range, lb. per sq. in......	250–400	400–600	600–1500

Flanges of flanged valves and fittings shall conform to American Standard B16e (see Table 48).

Fittings shall be cast or forged steel, but non-ferrous fittings may be used for temperatures under 500° F. Forged or cast-steel screw fittings may be used in sizes up to 3 in. for pressures above 250 lb. per sq. in. but not over 400 lb. per sq. in.; 1 1/2 in. above 600 lb. but not over 1500 lb. if their design is suitable for the pressure and temperature. Malleable-iron screwed fittings in accordance with the 300-lb. M.S.S.* Standard Practice SP–31 may be used for maximum pressures of 300 lb. and maximum temperatures of 500° F.

Valves shall be of cast or forged steel, or of forged or cast non-ferrous material if temperature is under 500° F. Malleable-iron valves may be used for service pressures not over 300 lb. per sq. in., and temperatures under 500° F. Stem threads may be internal or external with reference to the valve bonnet, which may be joined to the body either by screwed or flanged connections in the following sizes: 3 in. and smaller for pressures of 250 to 400 lb. per sq. in; 2 in. and smaller for pressures of 400 to 600 lb. per sq. in.; 1 1/2 in. and smaller for pressures of 600 to 1500 lb. per sq. in. Stem threads on valves larger than the above sizes shall be external to the valve body, and used in connection with a yoke and flanged bonnet. Steam valves 8 in. and larger shall have a 3/4-in. (minimum) by-pass of seamless steel of quality equal to A.S.T.M. specification A106 and of minimum weight equal to Schedule 80 of American Standard B36. (Table 14).

Pressures 125–250 lb. per sq. in., gage. Maximum Temperature, 450° F.—Steel flanged fittings shall conform to the 300-lb. American Standard B16e (Tables 44–48); cast-iron fittings shall conform to the 250 lb. American Standard B16b for flanged, and B16d for screwed fittings (Tables 34–38). Malleable-iron screw fittings shall conform to the 300-lb. M.S.S. Standard Practice SP–31 (Table 36), except that the 150-lb. American Standard B16c (Table 38) may be used in accordance with its table of adjusted temperature-pressure ratings. Bodies shall be of cast iron, malleable iron, steel, brass, bronze or Monel metal. Flanges of brass or bronze flanged fittings shall conform to M.S.S. SP–2 for 250 lb. Cast-steel fittings with welding ends shall conform, in material and thick-

* M.S.S. = Manufacturers Standardization Society of the Valve and Fittings Industry.

[1] Elongation in 4 in. [2] Zn = remainder. [3] Maximum. [4] Physical requirements not specified. Hydrostatic test required, sufficient to subject material to fiber stress of 6000 lb. per sq. in. as calculated by formula [8], C being taken as 0.

[5] If grade B or C pipe are to be joined by fusion welding, purchaser may wish to specify carbon content by special agreement. See A.S.T.M. specification A151 of steels suitable for fusion welding.

[6] 2400 lb. per sq. in. minimum. [7] 27,000 lb. per sq. in. minimum. [8] Acid. [9] Basic.

(Table 33). Gate, angle and globe valves smaller than 3 in. may have inside screw. Stop valves, 8 in. or larger, are to be by-passed. If pipe is used in by-pass, it is to be steel or wrought iron.

Steam Pressures 25–125 lb. per sq. in., gage. Maximum Temperature 450° F.—Fittings shall be of the 125-lb. American Standard, either screwed (A.S.A. B16d) or flanged (A.S.A. B16a) (Tables 36 and 38), or 150-lb. American Standard B16c, malleable iron (Table 38) or bronze (M.S.S. SP–10) (Tables 37–41). Flanges of bronze fittings shall be in accordance with M.S.S. SP–2 (Table 42). Cast-steel fittings shall conform, in material and thickness, to American Standard B16e for 150 lb. service pressure.

Valves shall have cast-iron, malleable-iron, steel or brass bodies, bonnets, discs, and yokes.

* Schedule Number indicates approximately values of $\{1000 \times (P/S)\}$. P = internal pressure, lb. per sq. in.; S = allowable fiber stress, lb. per sq. in.

150 lb. (Table 42). Cast-steel fittings with welding ends may be used if their material and wall thickness are suitable for this class of service.

Valves shall have cast-iron, malleable-iron or brass bodies, bonnets, discs, and yokes. Flanges shall conform to 25-lb. American Standard B16b2 (Table 33) for pipe sizes 4 in. and over, and to 125-lb. American Standard B16a (Table 33) for sizes under 4 in. Bronze or brass flanges shall be in accordance with M.S.S. SP–2 dimensions (Table 42) for 150-lb.

Pressure-Temperature Ratings of Fittings.—The A.S.M.E. Boiler Code requires that all valves and fittings shall at least equal the requirements of the American Standard for 125-lb. per sq. in. except where a higher pressure or steel construction is specifically required. The scheduled working pressure for steel fittings may be adjusted to actual maximum allowable working pressure by means of Table 16.

Pipe Joints

Pipe joints may be threaded, flanged or welded. Special joints are permissible under certain conditions.

Threaded joints shall conform to American Standard B2 for Taper Pipe Threads. Flanged joints may have: Flanges cast or forged integral with the pipe, fittings or valves; screwed companion flanges, permitted in sizes and for maximum service ratings covered by American Standards (see Tables 33, 42, 44, 45); steel flanges grooved for rolling in the pipe with an expanding tool, permitted in sizes and maximum service ratings for screwed companion flanges, the grooves being designed to carry the entire load of pressure and piping strains; lapped (Van Stone) flanges, permitted in sizes and maximum service ratings covered by integral flanges.

Lapped (Van Stone) Joints.—All cast-iron flanges for lapped joints shall have a high hub and the joint shall have an outside diameter of lap substantially equal to but not greater than the diameter formed by the innermost face edge of the bolt holes. All flanges for lapped joints shall have their faces machined true to provide an even bearing against the backs of the lapped pipe ends. Pipe for use with the 300-lb. American Standard B16e (Table 45) companion flanges may be lapped without upsetting to obtain a minimum thickness through the lap equal to the thickness of the pipe. Where a female tongue-and-groove ring joint, or ground joint facing, is machined in the lap, minimum thickness through lap shall not be less than thickness of pipe recommended for that service. Total clearance between bore of a lapped flange and the outside diameter of pipe, except for service pressures below 25 lb. per sq. in., shall not exceed the following:

Pipe size, in.	6 and less	8–12	14 and over
Maximum total clearance, in.	$^1/_8$	$^3/_{16}$	$^1/_4$

Flange Facing.—Plain flanges shall be faced smooth. Flanges with $^1/_{16}$-in. or $^1/_4$-in. raised face, may be used (Table 47). The gasket surface may be faced smooth or finished with concentric or special grooves, $^1/_{32}$ in. deep, 16 and 32 grooves per in. for cast iron, and steel, respectively, being recommended. Flanges with large male and female, or wide tongue-and-groove facing, may be used as covered by American Standards. The gasket surface may be smooth or have concentric or spiral grooves. The small male and female, or narrow tongue-and-groove, may be used in steel only as covered by American Standard B16e (Table 47). The gasket surface shall be finished smooth. Metallic gaskets are recommended. Ring-type joints having flange faces grooved for a soft steel ring gasket, ground-type joints with flange faces machined with a concave or conical seat to make a joint with a loose ring, or with a convex face on one of the flanges, and seal-welded-type joints are permitted with steel flanges only.

Gaskets of paper or vegetable fiber shall not be used for temperatures over 250° F., and only where this type of material is required to resist the action of the fluid. Rubber inserted gaskets may be used with plain-face flanges for temperatures not over 250° F. Asbestos composition gaskets may be used with any flange facing, except small male and female or narrow tongue-and-groove. Jacketed asbestos or metallic gaskets, either plain or corrugated, are not limited as to pressure or temperature.

WELDED JOINTS made by the fusion process may be butt or fillet welds. See Fig. 12. The Code covers joints formed by pipe end to end, pipe branches, pipe to flanges, fittings and valves, and pipe, valve or fitting to other equipment.

Materials for pipe, fittings, valves and flanges must conform to the requirements of the various sections of the Code. They must be of good weldable quality, free from laminations, harmful ingredients or defects. Filler metal, electrodes, welding wire, and welding rods shall be suitable for use with the base metals to be welded.

Butt Welds are those whose throat, *i.e.* the minimum thickness of the weld, not including reinforcement, along a straight line passing through the root, lies in a plane at approximately 90 deg. from the surface of at least one of the parts joined. In double welded joints, filler metal is added to both sides; in single welded joints it is added to one side only. Parts shall be prepared for fusion welding approximately as in Fig. 12. Welds may be single- or double-V type, or U-bevel. Welding procedure shall insure complete penetration of deposited metal to the bottom of the joint, and thorough fusion of deposited and base metal. Ferrules or backing strips inside the pipe may be used if properly secured and thoroughly fused to the weld. Minimum throat shall be the thickness of the thinner part joined. Welds shall be reinforced in excess of net throat not less than $1/16$ in. for material up to and including $1/2$ in. thick, and $1/8$ in. for thicker material.

Fillet Welds are of approximately triangular cross-section, with the throat in a plane at approximately 45 deg. from the surface of the parts joined. See Fig. 12. They may be either single or double fillet. Welding procedure shall insure complete penetration and thorough fusion of deposited and base metal. Minimum throat shall be 0.75 × nominal size of weld, *i.e.*, the width of the shortest of its adjacent fused legs.

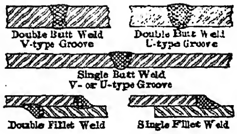

FIG. 12. Fusion Welds

Seal Welds are continuous arc or gas welds primarily intended to secure tightness. They may be either butt or fillet type, and should be made of as small cross-section as practicable. They shall not be considered as contributing to the strength of the joint. Seal welding must be so done as to avoid undue straining of the joint by temperature changes.

Cast Iron and Non-ferrous Materials shall be welded, when permitted, with bronze or other suitable filler metal. Copper pipe shall not be welded with copper welding rod, but may be welded with bronze rod; brass pipe also may be welded with bronze rod.

Flanges.—Fig. 13 shows designs of welds for steel flange connections. The slip-on flange is limited to service pressures not over 300 lb. per sq. in.

Welding Procedure.—Beveling preferably shall be by machine. Torch beveling may be used if the surfaces afterward are cleaned thoroughly from scale and oxidation. All surfaces must be free of paint, oil, rust and scale, except that a light coat of linseed oil to prevent rust is permissible. No part may be offset from an adjacent part by more than 20% of the pipe thickness. Length of tack welds shall be approximately twice the thickness of the thinner material joined. Tack welds must be kept below the outside surface, and melted out during welding. No globules of metal may project within the pipe so as to seriously restrict its area or cause danger of loosening and falling into the pipe. The thickness of reinforcement of butt welds shall increase gradually from edge to center, and no depressions below the surface of the pipe are permissible. Nozzles, tees and branches in materials of $3/4$ in. or more wall thickness shall be welded under shop conditions. Precautions must be taken to insure that welding operations do not cause distortion by heat that would prevent any valve, sliding fixture or other operating equipment from functioning properly.

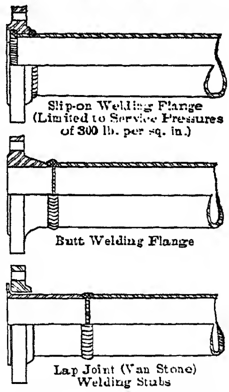

FIG. 13. Welds for Steel Flange Connections

Stress Relief shall be effected by uniformly heating joints to between 1100° and 1200° F., where the pipe wall is $3/4$ in. thick or more, and service temperature exceeds 250° F. The heated parts shall be brought slowly to the required temperature, held at this temperature for 1 hour per inch of wall thickness, and allowed to cool slowly in the atmosphere. The complete structure may be heated as a unit, or a complete section containing the weld may be heated before attachment to other sections of the work, or a circumferential band of minimum width of 6 × plate thickness on each side of the weld may be so heated that the entire band is brought to the required temperature and held there for the specified time.

The Code contains instructions for the testing of welded joints, and for determining the qualifications of welders.

SPECIFIC REQUIREMENTS FOR PIPE JOINTS for various services are abstracted below: Welded joints and joints other than welded to be in accordance with the Code (see above).

Steam Pressures Over 250 lb.–1500 lb. per sq. in., gage. Temperatures 450°–750° F.—Flanges and bolting to conform to American Standard B16e (Tables 44–46). Unions to be of forged steel and suitable for the pressure.

Steam Pressures 125–250 lb. per sq. in., gage. Maximum Temperature 450° F.—Flanges and bolting to conform to 300-lb. American Standard B16e (Tables 44–46), or 250-lb. American Standard B16b (Table 33) for steel and cast iron, respectively, and to M.S.S. Standard Practice SP-2b (Table 42) for bronze. The 150-lb. American Standard B16e may be used in accordance with its adjusted temperature pressure rating table. Unions shall be suitable for the pressure.

Steam Pressures, 25–125 lb. per sq. in., gage. Maximum Temperature 450° F.—Flanges and bolting to conform to 125-lb. American Standard B16a (Table 33) for cast iron, and to M.S.S. Stand-

ard Practice SP–2a (Table 42) for bronze. Unions to be suitable for temperature and pressure. Cast-iron pipe joints may be welded with bronze if service pressure is not over 125 lb. per sq. in., and temperature is not over 353° F.

Steam Pressure 25 lb. per sq. in., gage, and Less.—Maximum Temperature 450° F.—Companion flanges to conform to 25 lb. American Standard B16b2 (Table 33). Bronze flanges to conform to M.S.S. Standard Practice SP–2a (Table 42). Unions to be suitable for the pressure. Cast-iron pipe joints may be welded with bronze if temperature does not exceed 353° F.

EXPANSION of the more common piping materials shall be calculated on the basis of total expansion in inches per 100 ft. as follows:

Temp. °F.	32	100	150	200	250	300	350	400	450	500	550	600	650	700	750
	Expansion, in.														
Steel, Wrought iron	0	0.5	0.9	1.3	1.7	2.2	2.6	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5
Cast iron	0	0.5	0.8	1.2	1.6	1.9	2.3	2.7	3.1	3.5	...	...	...	...	...
Copper	0	0.8	1.4	2.0	2.5	3.1	3.7	4.3	4.9	5.6	...	...	...	...	...
Brass, Bronze	0	0.8	1.4	2.1	2.7	3.4	4.1	4.8	5.5	6.2	...	...	...	...	...

FLEXIBILITY OF PIPING SYSTEMS shall be sufficient to prevent thermal expansion from causing unsafe stresses in piping material, excessive bending moments at joints or excessive thrusts on equipment or at anchorage points. Flexibility shall be provided by changes of direction, or by bends, loops, offsets or expansion joints of slip or corrugated types. Under certain conditions flexibility may be increased by corrugating or creasing the pipe wall. Where pipe lines join, provision must be made for expansion of both branches. Pipe may be cut short by an amount approximately one-half the calculated expansion and sprung into place, but no reduction in expansion to be cared for shall be made on account of such cold springing. However, if a line lies between anchors in one plane, the effective expansion between anchors may be taken as $2/3$ of the computed expansion. In calculating flexibility, allowance must be made for the flattening effect in curved pipes.

PIPING SUPPORTS shall be designed to allow free expansion and contraction of pipe without causing excessive strains in pipe, anchors or supports. Supports shall permit side movement of pipe caused by normal expansion. Anchors and guides shall be located to confine and guide expansion in a direction permitting proper use of the flexibility of the system.

5. STRESSES IN PIPE LINES *

In the design of a piping structure the limiting features usually are the thrust that can be imposed on the members to which the piping is to be connected and the stress allowable in the pipe at the temperature at which it is to be used.

The first step, therefore, is to determine the thrust and stress on the proposed layout. Once these are determined it usually is possible to modify the design to meet the imposed conditions. If the design is too stiff and highly stressed it will be necessary to add length to some of the members, to add short lengths at right angles to each other on the plan of the U-bend or to use some kind of expansion joint if the space is limited.

Stresses encountered come under several headings:

1. Stress due to thermal expansion which can be determined by the graphical method.
2. Bursting or hoop stress which is found from the formula

$$S = pd/2t \qquad [9]$$

where p = pressure, lb. per sq. inch; d = inside diam. of pipe, in.; t = wall thickness of pipe, in.

3. Longitudinal stress due to internal pressure, which is equal to $1/2 \times$ (hoop stress).
4. Longitudinal bending stress due to the dead weight of unsupported lengths of piping. Stresses can be determined from beam formulas, and hangers properly spaced to reduce the stresses.
5. Stresses due to direct thrust or direct tension. These are equal to the direct forces divided by the net area of the pipe and usually are small.
6. Torsion. If the piping between anchor points is in one plane no torsion will be present. However, if the piping lies in more than one plane the points where torsion will occur can be located by inspection and the torsional stress calculated by consideration of the forces applied.

In calculating the stresses due to thermal expansion the modulus of elasticity used should be selected for the temperature at which the pipe is to be used. The value of the modulus drops rapidly with rise in temperature. The proper value can be derived by the formula of G. A. Orrok (High Pressure Steam Boilers, *Trans.* A.S.M.E., FSP–50–28, 1928),

$$E_t = E_{32}\left[1 - \{(t - 32)/1700\}^2\right] \qquad [10]$$

where E_{32} = modulus of elasticity of the material at 32° F.; t = temperature at which the modulus is required; E_t = modulus of elasticity at temperature t.

---

* Contributed by A. S. McCormick.

If the pipe is to operate at a temperature below the creep range, that is below 750° F., the stress may be reduced as much as 50% by cold setting or springing. If the working temperature is above 750° F. it will be found best to set up the pipe without any cold strains, provided that the stress during the first heating-up cycle does not exceed the elastic limit of the material for the temperature attained. Creep action will reduce the strains to a minimum for the temperature cycle and the remaining stress will appear in the opposite direction when the pipe is cooled. The use of pipe made of material which has good creep strength should be considered in high-temperature installations.

A GRAPHIC METHOD FOR DETERMINING STRESSES IN PIPING is given by C. T. Mitchell in *Trans.* A.S.M.E., FSP-52-25, 1930. Being graphic, it is independent of tables and complicated formulas. It considers the pipe structure as a whole, and is applicable to any independent pipe structure in one or more planes.

Two assumptions are made in every problem: 1. The ends or anchor points are assumed to be 100% fixed. 2. The moment of inertia of the pipe is assumed to be constant, whether the section be taken at a bend or elsewhere. No attempt is made to determine the horizontal or vertical reactions at anchor points. Also, all bends are eliminated from the structure during the analysis, and square corners substituted in their place. A correction subsequently is made for the influence of bends.

Notation.—A, B, C, F, G, H, J = moment areas, sq. ft.; a, b, c, f, g, h, j, l, m, n, o = distances on sketches, ft.; D = outside diam. of pipe, in.; d = inside diam. of pipe in.; Δ = expansion of pipe between anchors, in.; E = modulus of elasticity; I = moment of inertia, in.^{4}; $M = \Sigma$(moment areas $\times$ distance of center of gravity of each to neutral axis), *i.e.*, $M = \Sigma(Aa + Bb + Cc + \ldots)$; P = thrust between anchors, lb.; P_c = thrust corrected for bends in pipe, lb.; R = shortest distance from neutral axis to point of greatest bending moment, ft.; S = stress in outside fiber of pipe, lb. per sq. in.; T = total length of pipe with square corner bends, ft.; t = total length of pipe with full radius bends, ft.

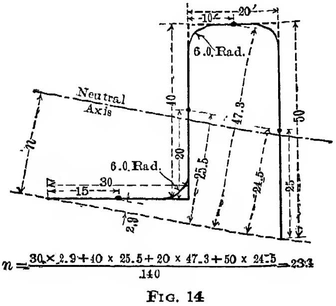
The application of the method will be illustrated by a problem wherein the pipe is in a single plane, and one wherein it is in two planes.

Typical Single-plane Problem.—Arrangement of piping is shown in Fig. 14. Conditions: 12-in. pipe, wall thickness, 1.219 in.; D = 12.75 in.; I = 740.0; steam temperature, 750° F.; room temperature, 70° F.; expansion of steel pipe through 680° F., 7.20 in. per 100 ft.

The procedure is as follows: 1. Redraw the arrangement to a convenient scale, with square corners instead of bends (dotted lines, Fig. 14). 2. Locate neutral axis as shown in Fig. 14. 3. Draw moment areas A, B, C, F, G, H as in Fig. 15. 4. Compute the square feet in these areas, as below. The sum of the areas on each side of the neutral axis should be equal.

$$\begin{aligned}
A &= 1/2\{(23.4 + 17.6) \times 30\} &&= 615\\
B &= 1/2\,(17.6 \times 17.9) &&= 158\\
C &= 1/2\,(21.9 \times 22.1) &&= 242\\
F &= 1/2\,\{(21.9 + 25.6) \times 20\} &&= 475\\
G &= 1/2\,(25.6 \times 26.2) &&= 335\\
H &= 1/2\,(23.4 \times 23.8) &&= 279
\end{aligned}$$

5. Compute M. $M = Aa + Bb + Cc + Ff + Gg + Hh$ = (615 × 20.8) + (158 × 11.7) + (242 × 14.4) + (475 × 24.0) + (335 × 16.8) + (279 × 15.7) = 39,545. 6. Compute P. Dis-



$$n = \frac{30 \times 2.9 + 40 \times 25.5 + 20 \times 47.3 + 50 \times 24.5}{140} = 23.4$$

FIG. 14

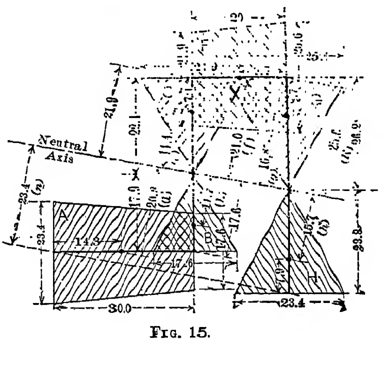


FIG. 15.

tance between anchors = 51.0 ft. Consequently, $\Delta = (7.20 \times 51)/100 = 3.68$ in., and $P = \Delta EI/1728\ M = (3.68 \times 29{,}000{,}000 \times 740.0)/(1728 \times 39{,}545) = 1160$ lb. $P_c = PT/t = 1160 \times 140/132.2 = 1230$ lb. 7. Compute S. The greatest stress in the pipe line is located at a point at the greatest distance from the neutral axis. By scaling Fig. 15, this distance is found to be $R = 25.6$ ft. Then by substitution in the formula

$$S = 6\, P_c RD/I \qquad [11]$$

we find $S = (6 \times 1230 \times 25.6 \times 12.750)/740 = 3250$ lb. per sq. in. The stress may be calculated at any point along the pipe by scaling the perpendicular distance from this point to the neutral axis, and substituting the value so found for the value of R in formula [11].

Typical Two-plane Problem.—Arrangement of the piping is shown in perspective in Fig. 16. Conditions: 6-in. pipe, wall thickness, 0.5 in.; $D = 6.625$ in.; $I = 45.4$; steam temperature, 750° F.; room temperature, 70° F.; expansion of steel pipe through 680° F., 7.20 in. per 100 ft.

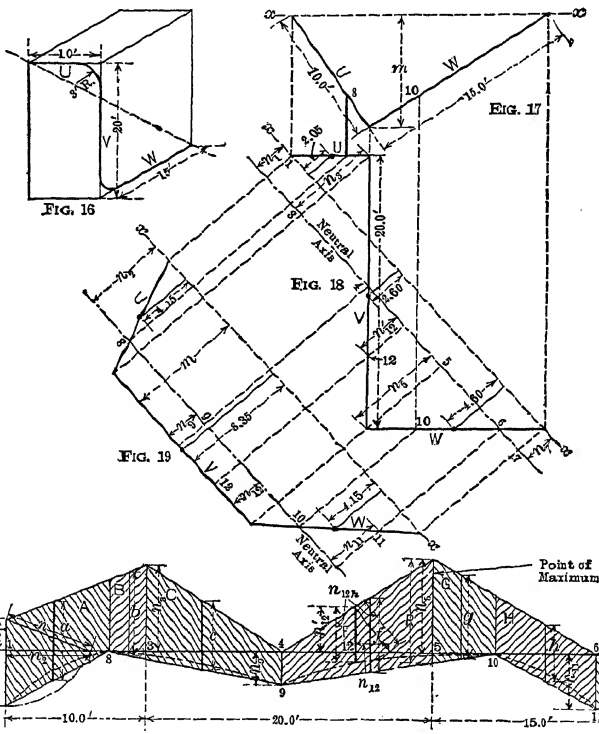

FIG. 16 FIG. 17 FIG. 18 FIG. 19

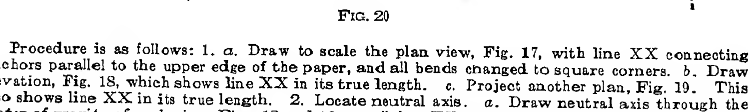

FIG. 20

Procedure is as follows: 1. *a*. Draw to scale the plan view, Fig. 17, with line XX connecting anchors parallel to the upper edge of the paper, and all bends changed to square corners. *b*. Draw elevation, Fig. 18, which shows line XX in its true length. *c*. Project another plan, Fig. 19. This also shows line XX in its true length. 2. Locate neutral axis. *a*. Draw neutral axis through the center of gravity of each view, Figs. 18 and 19, parallel to XX, taking care to use the true length of each pipe member in the calculations. Let U, V, W be the true length of the several pipe members, and u, v, w, respectively, the perpendicular distance from the mid-point of each member to the neutral axis. Let n = distance of neutral axis from the center of gravity of the system. Then

$$n_1 = (Uu_1 + Vv_1 + Ww_1)/(U + V + W).$$

and

$$n_2 = (Uu_2 + Vv_2 + Ww_2)/(U + VW)$$

If the mid-points of the several sections lie on the same side of the line XX, the products Uu, Vv,

Ww will be of like algebraic sign. If they lie on opposite sides of XX, the products will be of unlike sign.

$$n_1 = \{(10 \times 2.05) - (20 \times 2.60) - (15 \times 4.60)\}/45 = -\ 2.23 \text{ ft. (Fig. 18)}$$

$$n_2 = \{(10 \times 4.15) + (20 \times 8.35) + (15 \times 4.15)\}/45 = +\ 6.02 \text{ ft. (Fig. 19)}$$

3. Draw moment areas A, B, C, F, G, H, J, as shown in Fig. 20. *a.* To determine moment areas, it is necessary to know the perpendicular distance from the neutral axis to all parts of the piping arrangement. The distance for any point is the hypotenuse of a right triangle, the legs of which are the ordinates to the neutral axis from the point in question, which may be scaled from the drawings, Figs. 18 and 19. *b.* Draw the moment areas about the line YY, Fig. 20. This line represents the total length of pipe, with each member drawn to scale. Above YY, and perpendicular to it, draw the ordinates for the end of each member, as scaled from Fig. 18. These are drawn *above* YY, irrespective of their position in Fig. 18. Connect the ends of the ordinates by straight lines. The irregular dotted line below YY is so drawn that at any point the vertical distance between it and the line above YY is the bending moment at that point. This is done by laying out on YY a right triangle, whose base along YY is the ordinate to the neutral axis as scaled from Fig. 18, and whose altitude is the ordinate to the neutral axis as scaled from Fig. 19; the hypotenuse is the bending moment. The length of the hypotenuse, measured on a line perpendicular to YY through the given point, from the upper line of the moment diagram gives a point on the lower line of the diagram. See point n_{12} on Fig. 20, and the corresponding points on Figs. 18 and 19. Where the pipe intersects the neutral axis in Fig. 18, the ordinate at that point is, of course, zero, and the position of the point in the lower line of the moment diagram is determined by the length of the ordinate in Fig. 19. See points 9 and 11 in Figs. 18, 19 and 20. It is unnecessary to plot a large number of bending moments. The dotted line, forming the true boundary of the moment diagram, is a refinement that is not worth while. Using the trapezoidal areas A, B, C, etc., instead of the true moment area will give results that are sufficiently accurate. In locating points along YY in Fig. 20, the true distance along the pipe member under consideration should be taken, as determined by projecting the point to Fig. 17 or 18 as may be necessary. See point 8, which is projected from Fig. 19 to Fig. 17, to find its correct position in Fig. 20.

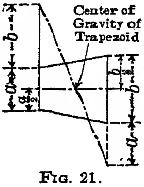

Fig. 21.

4. The next step is to divide the total moment area into a convenient number of trapezoids as A, B, C, F, G, H, and J, and to compute the square feet in each area. Scaling the bases and altitudes of the several trapezoids in Fig. 20, we find the areas to be

$$A = 1/2\,(6.4 + 5.2) \times 7.2 = 41.7$$
$$B = 1/2\,(5.2 + 6.9) \times 2.8 = 17.0$$
$$C = 1/2\,(6.9 + 2.3) \times 9.5 = 43.7$$
$$F = 1/2\,(2.3 + 7.7) \times 10.5 = 52.5$$
$$G = 1/2\,(7.7 + 4.5) \times 4.2 = 25.6$$
$$H = 1/2\,(4.5 + 4.0) \times 7.1 = 30.2$$
$$J = 1/2\,(4.0 + 6.4) \times 3.7 = 19.3$$

5. Next compute M. The lengths of lines a, b, c, f, g, h, j are determined by locating the center of gravity of each trapezoid, as shown in Fig. 21, drawing a perpendicular to YY through each center of gravity, and scaling the intercept between the sides of the trapezoid. Then

$$M = Aa + Bb + Cc + Ff + Gg + Hh + Jj = (41.7 \times 5.8) + (17.0 \times 6.1) + (43.7 \times 5.0)$$
$$+ (52.5 \times 5.4) + (25.6 \times 6.2) + (30.2 \times 4.1) + (19.3 \times 5.2) = 1237.$$

6. Compute P. Distance between anchors = 26.9 ft., and $\Delta = (7.20 \times 26.9)/100 = 1.94$ in. Then $P = \Delta EI/1728\,M = (1.94 \times 29{,}000{,}000 \times 45.4)/(1728 \times 1237) = 1195$ lb.

$$P_c = PT/t = (1195 \times 45)/42.6 = 1260 \text{ lb.}$$

7. Compute S. The maximum strain occurs at the point of greatest bending moment. This point is shown in Fig. 20, and the distance R is found to be 7.7 ft. Substituting in formula [11].

$$S = (6 \times 1260 \times 7.7 \times 6.625)/45.4 = 8500 \text{ lb. per sq. in.}$$

The stress may be calculated at any point along the pipe line by scaling the ordinate at this point in Fig. 20, and substituting the value so found for R in formula [11].

Correction for Square Corners can be made by multiplying the values obtained for Δ in the above analysis by the factor

(Total length of actual structure) ÷ (Total length of square-corner structure).

Results will be 90 to 100% accurate, which is all that reasonably can be expected in problems of this character, in view of the uncertainties always present. If allowance is made for flattened cross-section of the pipe at bends, it should be remembered that the factor of safety of the structure therby is lowered.

In two-plane problems the stress may be due to a combination of torsion and bending. Mr. Mitchell explains in the paper why the stress may be treated as a simple bending stress, and also explains the development of the correction factor for square corners. The theory underlying the graphic method is demonstrated.

6. COMMERCIAL PIPE AND TUBING

Tables 17 to 32 give data on steel, wrought-iron and non-ferrous pipe commercially available for steam service, and also on seamless tubes and boiler tubes.

STEEL WELDED PIPE is furnished with threads and couplings and in random lengths unless otherwise ordered. Permissible variation in weight is ±5% of the weights given in Tables 17–19. Weights are based on 1 cu. in. of steel = 0.2833 lb., and on 20-ft.

WROUGHT-IRON WELDED PIPE has a thicker wall and smaller internal diameter than welded steel pipe. It is furnished with threads and couplings, and in random lengths. Permissible variation in weight is +5% and −2 1/2% from the weights given in Tables 20 and 21.

SEAMLESS STEEL TUBES are both hot and cold drawn. Composition of the various grades of steel used are given in Table 22. Physical properties of cold-drawn tubing are given in Table 23. Weights are given in Tables 24 and 25. Table 26 gives the dimensions of standard seamless and lap-welded steel boiler tubes, and Table 27 of seamless steel locomotive boiler tubes. Weights are based on 1 cu. in. of steel = 0.2833 lb. These tables were compiled from data supplied by the National Tube Co., Pittsburgh.

* Test pressure for all tubes in this table is 1000 lb. per sq. in.

SEAMLESS BRASS TUBES are made from 1/16 in. to 1/8 in. outside diameter, varying by 1/64 in., in all gages from No. 23 to 36 Stubs gage; from 1/8 in. to 5/16 in., varying by 1/32 in., gages from 18 to 36; from 3/8 to 5/8 in., varying by 1/16 in., gages 16 to 35; from 3/4 to 1 in., varying by 1/8 in., gages 8 to 30; from 1 1/4 in. to 7 3/4 in., varying by 1/4 in., gages 1 to 24; from 8 to 10 in., varying by 1/2 in., gages 3 to 16. To determine the weight

of a tube of a given inside diameter, add to the weight for the outside diameter and gage given in Table 28 the weight given below for the corresponding wall thickness.

Thickness, Stubs Gage..........				8	10	12	14	16	18	20	22	24	26

* Lengths advance by 1/2 in. up to and including 6 in.; 8 in. and 10 in. sizes advance by 1 in.

STANDARD PIPE THREADS.—(American Standards Assoc., 1919). The dimensions of standard pipe threads are given in Table 31. The formulas for these dimensions are:

Pitch diameters.— $A = D - (0.05\,D + 1.1)P$; $B = A + 0.625\,F$;
Length of thread.— $E = (0.80\,D + 6.8)P$,

where A = pitch diameter at end of pipe; B = pitch diameter at gaging notch: D = out-

side diameter of pipe; E = length of effective thread; F = normal engagement by hand between male and female threads; P = pitch of thread = distance axis will advance in one revolution, expressed in threads per inch. All dimensions are in inches. See Fig. 22.

Taper of Thread, 1 in 16, measured on the diameter.

Manufacturing Tolerance.—The maximum allowable variation in the commercial product is one turn plus or minus from the gaging notch when using working gages. Due to an allowance of 1/2 turn on the working gages, this is a maximum allowance of 1 1/2 turns from the basic dimensions.

Form of the Thread.—The included angle of the thread is 60°, measured in the axial plane. The thread is perpendicular to the axis of the pipe for both straight and taper threads. The crest and root are truncated an amount = 0.033 P, and the depth of thread is 0.80 P.

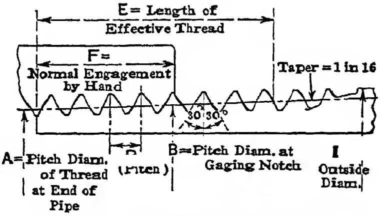

Fig. 22. American Standard Pipe Thread

Length of Thread, as given by the formula, is the effective length, and includes two threads that are imperfect on the crest. In this the formula differs from the original Briggs formula, which determined the number of perfect threads. The Briggs formulas

Table 31.—Dimensions of American Standard Pipe Threads

which are expressed in different terms than those of the American standard, give identical results with the latter. For a statement of the Briggs formulas, see earlier editions of this book.

Types of Threads.—Taper male and female threads are recommended for threaded joints for any service. Straight threaded female standard-weight couplings may be used with taper threaded pipe for ordinary pressures. For high pressure, only taper male and female threads should be used. Straight male threads are applicable only to special purposes, as long screws and tank nipples. Long screw joints are not satisfactory when subjected to temperature or pressure. In this application the coupling has a straight thread and must make a joint with an American taper pipe thread.

The straight thread of the largest diameter it is possible to cut on a pipe has been standardized under the name of Maximum Male and Minimum Female Locknut Threads. An American standard taper thread is cut on the end of the pipe after having cut the male locknut thread.

Dimensions of the various applications noted above are given in Table 31.

7. PIPE FITTINGS

Pipe Fittings of steel, cast iron, malleable iron and bronze are authorized by the Code for Pressure Piping, with limitations imposed by the service in which they are to be used. Tables 33 to 48 give dimensions of various types and classes of fittings according to the standards of the American Standards Association and the Manufacturers Standardization Society of the Valve and Fitting Industry. The following notes are abstracted from the specifications of the American Standards Association.

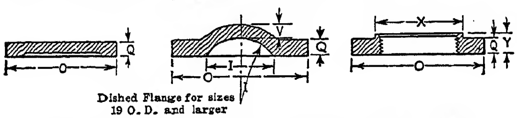

FIG. 23. Cast-iron Companion and Blind Flanges, 125-lb.

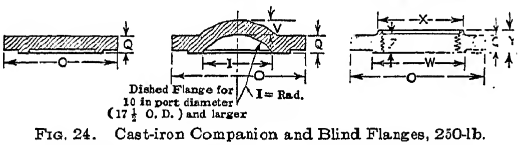

FIG. 24. Cast-iron Companion and Blind Flanges, 250-lb.

In designating the outlets of reducing fittings, the openings should be given in the order indicated by the sequence of the letters *abcd* in Fig. 27. In side outlet fittings, the side outlet is named last. In tees and crosses, run openings are given first and side openings next, the largest dimension being given first in each case.

Cast-iron Fittings.—Physical and chemical requirements for material for flanged fittings for 125 lb. and 250 lb. maximum pressure are: Maximum sulphur, 0.12%; minimum tensile strength, light castings, 20,000 lb. per sq. in.; medium castings, 21,000 lb. per sq. in.; heavy castings, 24,000 lb. per sq. in. For 25 lb. maximum pressure, maximum phosphorous, 0.75%, maximum sulphur, 0.12%; minimum tensile strength, 21,000 lb. per sq. in. Light castings are defined as those in which any section is less than 1/2 in. thick; heavy castings, no section less than 2 in. thick; medium castings, those not included in heavy or light classes. If the fittings are used in non-shock hydraulic work, the following maximum working pressures, lb. per sq. in. may be used: 250-lb. fittings, 10-in. and smaller, 325 lb. at 250° F.; 400 lb. at atmospheric temperatures; 125-lb. fittings, 12 in. and smaller, 175 lb. at atmospheric temperature; 25-lb. fittings, 36 in. and smaller, 43 lb. at atmospheric temperature. All 25-lb. and 125-lb. flanges are plain faced. All 250-lb. flanges have a 1/16-in. raised face; diameters are given in Table 33. Inspection limits of flanged fittings are: 25-lb. fittings, ±1/16 in. on center-to-face dimensions, and ±1/8 in. on face-to-face dimensions; 125-lb. and 250-lb. fittings, ±1/32 in. on center-to-face dimensions of 10-in. fittings and smaller, and ±1/16 in. on sizes over 10 in.; ±1/16 in. on

face-to-face dimensions of 10-in. fittings and smaller, and ±1/8 in. on sizes over 10 in. Inspection limits of center-to-end dimensions of screwed fittings are

Metal thickness of screwed fittings shall not be more than 10% below the minimum as given in the tables.

Drilling templates for flanges are made in multiples of four so that fittings may face in any quarter. Bolt holes straddle the center line and are drilled larger than the bolts,

size of

utlet. Sizes 18 in. and larger, reducing on outlet, are made in
outlet. See Table 35. † Applies only to elbows, tees and crosses.

as shown in Table 33. Bolt holes are not spot faced for ordinary service, but when required, flanges in sizes 36 in. and larger may be spot faced or back faced to minimum thickness of flange with a tolerance of $\pm ^1/_8$ in.

Screwed fittings are threaded according to American Standard Pipe Threads (A.S.A. B3–1919, or its latest revision), and variations in tapping and dieing are limited to one turn either way from the standard. See Table 31.

Malleable Fittings.—The same inspection limits apply to both malleable and cast-iron screwed fittings. The addition of lugs or ribs is permitted.

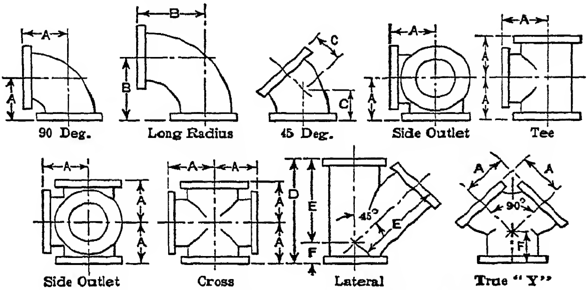

Fig. 25. Cast-iron Straight Size Fittings

Standard Bronze Flanges.—(Adopted May, 1930, by Manufacturers Standardization Society of Valve and Fittings Industry.) Dimensions of standard bronze flanges for valves and fittings are shown in Fig. 33 and Table 42. The material, known as steam-bronze, has the following percentage compositions:

	Cu (min.)	Sn + Zn (min.)	Pb (max.)	Tensile Strength lb. per sq. in. (min.)	Elong. in 2 in.,% (min.)
Grade A......	83.0	8.0	6.0	27,000	15
Grade B......	84.0	9.0	2.5	32,000	15

Carbon steel bolts should have tensile strength of 55,000 lb. per sq. in. (min.) and yield point of 28,000 lb. per sq. in. (min.). If non-corrosive bolts are required the material should have minimum physical properties equal to the required carbon steel bolts. The maximum temperatures that may accompany a given pressure and service condition are:

		Steam	Water	Gas or Liquid	Hydrostatic Tests: Seats	Hydrostatic Tests: Shells
150-lb. Valves	Pressure, lb. per sq. in....	150	200	225	225	375
	Temp., Grade A, deg. F...	366	300	150	125	125
	Temp., Grade B, deg. F...	500	350	150	125	125
250 lb. Valves	Pressure, lb. per sq. in....	250	300	375	375	625
	Temp., Grade A, deg. F...	406	325	150	125	125
	Temp., Grade B, deg. F...	500	350	150	125	125

The faces of flanges should be machined to a smooth finish over their entire face, and two concentric gasket-retaining rings not over $^1/_{16}$ in. deep, and $^1/_{16}$ in. wide, are recommended. Gaskets should be of same diameter as flanges and should be non-metallic.

Raised Faces.—The American Standards provide that all steel and cast-iron flanged valves and fittings shall have raised faces, as follows: 150- and 300-lb. standard, $^1/_{16}$ in. on all sizes, included in the minimum flange thickness; all other standards, $^1/_4$ in., on all sizes, added to the minimum flange thickness; outside diameters of raised face of steel flanges are given in Table 48 and of cast iron flanges in Table 33. Bottom or contact surfaces of groove and female facings are in the same plane as the edge of the flange. Outside diameters of groove and female are to be $^1/_{16}$ in. larger than corresponding outside diameters of tongue and male. A tolerance of ± 0.016 is allowed on inside and outside diameters of all facings. Gaskets for male-female and tongue-groove joints should cover the bottom of joint with minimum clearances. Drilling templates are in multiples of four, and bolt holes straddle the center lines. Bolt holes are drilled $^1/_8$ in. larger diameter than nominal size of bolts. Bolts, or bolt studs threaded at both ends, may be used, with cold-punched or cold pressed semi-finished nuts, American

Standard rough dimensions, chamfered and trimmed. From 1/2 in. through 1 in. diameter, American (National) standard coarse screw thread is used. Over 1 in. diameter, special threads of American form are used, with a pitch of 8 threads per inch. Bolt studs, with a nut on each end are recommended for high temperature work. All flanges are spot faced or back faced parallel to the flange face, except on forged steel flanges where the back

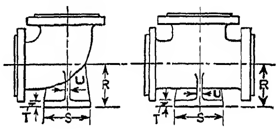

Fig. 26.

* These dimensions apply to straight and reducing sizes and long and short body patterns.

is parallel to the face. Spot facing must not reduce the thickness of the flange below that given in the tables.

Minimum metal thicknesses are based on an allowable fiber stress of 7000 lb. per sq. in., using the modified Barlow formula:

For pipes 1/4 to 5 in. diameter,

$$P = (2S/D)(t - 0.065) - 125,$$

and for pipes over 5 in. diameter, $P = (2S/D)(t - 0.1)$, where P = working pressure, lb.

per sq. in., t = thickness of pipe wall, in., D = actual outside diameter of pipe, in., S = fiber stress = 7000 lb. per sq. in.

An inspection limit of $\pm 1/32$ in. is allowed on all center to contact surface dimensions, and of $\pm 1/16$ in. on all contact surface to contact surface dimensions on all sizes to and including 10 in. The corresponding limits for sizes over 10 in. are $\pm 1/16$ in. and $\pm 1/8$ in., respectively. Reducing fittings have the same center to flange edge dimensions as straight size fittings corresponding to the largest opening.

Steel Flanged Fittings.—Physical and chemical requirements of material are given

* Malleable fittings only. † Cast iron fittings only.

in Table 44. Nuts are of carbon steel. Washers are of forged or rolled carbon steel. Dimensions of companion flanges are given in Tables 45 and 46. Dimensions of fittings are given in Tables 47 and 48. The dimensional standards for steel castings are based on a product equal to that given in A.S.T.M. specification A95–29 for carbon steel castings for valves, flanges and fittings. For high temperature, castings shall be heat treated. Dimensional standards for steel forgings, other than companion flanges, are based on a product equal to Class C steel given in A.S.T.M. specification No. A105–28 for forged or rolled steel pipe flanges for high temperature service. Class A steel shall be used for forge welding. Class B steel may be used for companion flanges with hubs and is acceptable for fusion welding. Class B steel shall be used for companion flanges when made without hubs. Table 44 is based on the above-named A.S.T.M. specifications.

* A raised face of 1/16 in. is included in min. thickness of flange of 150- and 300-lb. flanges, but is not included in the flanges for higher pressures. † This dimension is for large end of hub, which may be tapered 5 deg. for draft. ‡ For sizes below 2 in., use dimensions of 600-lb. flanges. § For sizes below 4 in. use dimensions of 600-lb. flanges. ¶ For sizes below 3 in., use dimensions of 1500-lb. flanges.

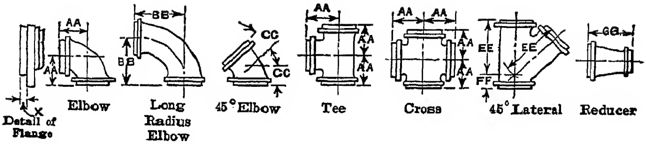

FIG. 36.

Table 46.—Dimensions of Steel Flanged Fittings, with Projecting Faces

American Standards Association (A.S.A. B16e, 1939)

All dimensions in inches. See Fig. 36. For dimensions of Base Fittings see Table 47. For dimensions of Faces, see Table 48.

Nominal Pipe Size	Fitting: Inside Diameter	Fitting: Min. Thick-Metal	Flange: Outside Diameter	Flange: Min. * A raised face of 1/16 in. (dimension *X*) is provided on the flange of each opening of the 150-lb. and 300-lb. fittings and is included in the minimum flange thickness, center to contact surface, and contact surface to contact surface dimensions. Reducing fittings have the same center to contact surface dimensions as straight fittings of the largest opening. On the 400-lb., 600-lb., 900-lb., 1500-lb., and 2500-lb. fittings a raised face of 1/4 in. (dimension *X*) *is not* included in the minimum flange thickness, but *is* included in the center to contact surface, and contact surface to contact surface dimensions. When facings other than the 1/16-in. and 1/4-in. raised faces, as given above, are used, the center to flange edge dimensions shall remain unchanged and new center to contact surface or contact surface to contact surface dimensions shall be established to suit the facing used.

Table 47.—Dimensions of Steel Flanged Base Fittings (A.S.A., B16e, 1932)

For dimensions not given see Table 46. All dimensions in inches. See Fig. 26.

Nominal Pipe Size	Center to Base *R*	Diameter of Base † *S*	Thickness of Base *T*	Thickness of Ribs *U*	Drilling for Base: Diameter of Bolt Circle	Drilling for Base: Number of Bolts	Drilling for Base: Size of Bolts
For 300 and 400 lb. per sq. in. at 750° F. For sizes below 4 in. in the 400-lb. fittings use the dimensions of 600-lb. fittings.

Table 49.—Facing Dimensions for Ring-joint Flanges—*Continued*

Nominal Pipe Size	Pitch Diam., Ring and Groove	Width of Groove	Depth of Groove L †	Diam. of Raised Face, Ring or Lapped Joint	Ring No. See Table 50	Approx. Distance between Flanges ‡
			For 2500 lb. per sq. in.			
	1 11/16		7/32	2 9/16	R 13	
	2		7/32	2 7/8	R 16	/32
	2 3/		7/32	3 1/	R 18	5/32
	2 27/32			4	R 21	1/8
	3 1/4			4 1/2	R 23	1/8
	4			5 1/4	R 26	1/8
2 1/2	4 3/			5	R 28	1/8
3			3/8		R 32	1/8
4			7/16		R 38	5/32
5			1/2	9	R 42	5/32
6			1/2	11	R 47	5/32
8	11		9/	13 3/8	R 51	3/16
10	13 1/2			16 3/4	R 55	1/4
12	16			19 1/2	R 60	5/16

† Depth of groove is added to minimum flange thickness Q. See Table 45.
‡ For ring joints when joint is compressed. This dimension must be added in calculating "laying lengths."
§ For ring joints with lapped flanges make P = 4 5/8 in. and use ring R30.

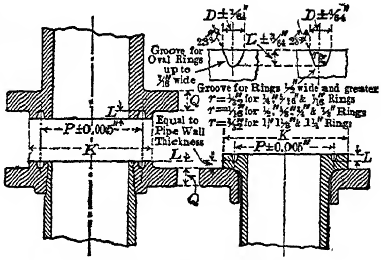

FIG. 38. Ring-joint Flange

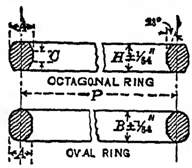

FIG. 39. Rings for Ring Joints

Table 50.—Dimensions of Rings for Ring Pipe Joints

A.S.A., B16e, 1939 and A.P.I., 5G3, 1937 Standards

P = pitch diameter of ring; A = width of ring; B = height of oval ring; H = height of octagonal ring; C = height of flat on octagonal ring. See Fig. 39. All dimensions in inches.

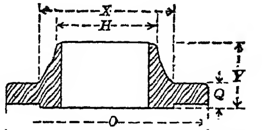

FIG. 40. Steel Welding Neck Flange

8. PIPING DETAILS

EXPANSION IN PIPING is provided for by the flexibility of the piping system as a whole, expansion bends, expansion joints, and by so introducing changes of direction that expansion will swivel the pipe in screwed fittings. Walker and Crocker (Piping Handbook) give the following formula for the expansion of piping:

$$L_t = L_0[\{1 + a(t - 32)/1000\} + b\{(t - 32)/1000\}^2],$$

where L_t, L_0 = length at temperature t and at 32° F., respectively; t = final temperature of pipe, deg. F.; a, b = constants whose values are:

	a	b
Cast Iron....	0.005441	0.001747
Steel.........	0.006212	0.001623
Wrought Iron.	0.006503	0.001622
Copper	0.009278	0.001244

The curves of Fig. 41 have been derived from this formula.

Stresses caused by expansion may exceed those due to the internal fluid pressure. In high-temperature work, creep stress also must be considered. Maximum permissible stress resulting from internal pressure, expansion, and dead weight between supports is 15,000 lb. per sq. in., up to temperatures of 700° F., with a reduction for higher temperatures. See p. 5–28.

* Type C only.

installed or the lineal feet of pipe for which each joint will compensate is determined by the traverse or movement of the joint. Table 52 gives the traverse of single-slip joints, and Table 53 the expansion and dimensions of corrugated copper expansion joints.

A corrugated copper expansion joint with standard flanges will withstand 125 lb. per sq. in. working pressure. With extra heavy flanges it will withstand a maximum of 250 lb. per sq. in. working pressure. A copper expansion joint never should be installed with superheat unless fitted with Monel metal sleeves. An expansion joint will not function properly unless the pipe line is securely anchored and has the required number of pipe guides. Anchors should be placed between every pair of joints and at every elbow.

Fig. 43. Corrugated Expansion Joint

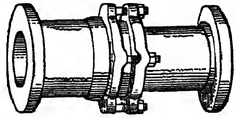

Fig. 44. Single Slip Expansion Joint

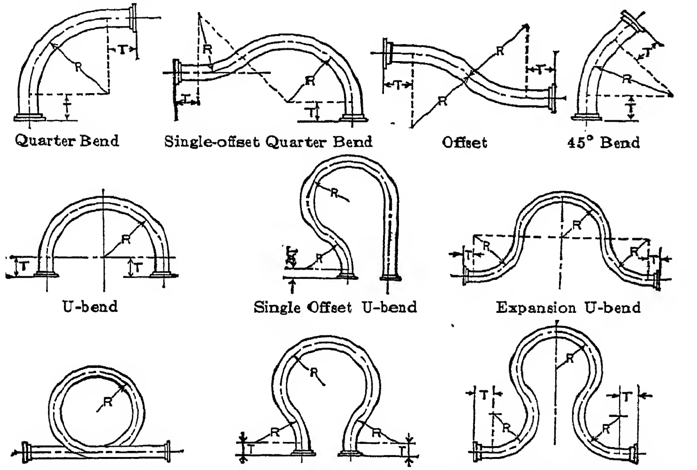

Fig. 45. Pipe Bends

Expansion Bends are of various forms as shown in Fig. 45 and Table 54. For extreme flexibility bends are corrugated or creased. The expansion taken up by expansion bends

Table 55.—Expansion Taken Up by Pipe Bends

(Crane Co., Chicago, 1929)

Figures in the table give the expansion, in inches, in a pipe line taken up by a quarter bend. To obtain the expansion taken up by other types of bends, multiply values in table by the following factors: U-bends, multiply by 2; single offset bends or expansion U-bends, multiply by 4; double offset bends, circle bends, or double offset expansion U-bends, multiply by 5.

Pipe Size, in.	Mean Radius of Bend, in.

is given in Table 55. These values may be large, and at high temperatures may introduce undesirable stresses in the pipe. They should be checked by a mathematical analysis of the pipe line as a whole before being accepted for design.

VAN STONE PIPE JOINT.—The original Van Stone joint was produced by expanding and turning over the end of the pipe, the resulting flange providing a bearing for a loose steel flange in which the bolt holes were drilled. The present form, as made by the M. W. Kellogg Co., New York is shown in Fig. 46. The upset end of the pipe is made of the same thickness as the pipe itself, but can be made as much thicker as desired, up to 200 percent of the pipe thickness. The square corner is formed in the upsetting process. The fillet radius on the back of the joint and on the face of the loose flange are concentric, thus bringing the bearing of the flange on the joint as close as possible to the pipe, and reducing the lever arm, tending to bend the joint, to the distance of the clearance between the pipe and flange. Flanges are made to the dimensions of the American Standard for flanged fittings. The radius of the fillet on the back of the joint is 3/8 in. for all sizes of pipe. The following clearances are allowed between pipe and flange: Pipe sizes 2 to 6 in. inclusive, 3/64 in.; 7 to 12 in. inclusive, 1/16 in.; 14 in. O.D. and larger, 5/64 in.

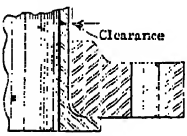

FIG. 46. Van Stone Joint

BENT AND COILED PIPE.—Table 56 shows minimum dimensions of pipe bends and coils. Machine-made bends of a single radius must be flat in one plane. Consecutive bends should have a straight portion at least equal to diameter of pipe between them. Coils requiring more than one length of tube or pipe cannot be made of as small diameter as those requiring no joints. The position or type of ends often limits the size of coils, and manufacturers should be consulted in unusual cases. The limiting factors for bends

10	42	66	72	114	6						
12	48	75 1/2	84	133	6						

* The radii given are to the center of the pipe. Radii can be reduced below those given in the table by the use of extra heavy pipe. Under usual circumstances steel pipe can be bent to a smaller radius than iron pipe.

in steel, brass or copper tubes are as follows, the outside diameter of the pipe being multiplied by the factor to obtain the desired dimension:

	Least Ordinary	Difficult	Limit
Center radius, 90-deg. bends...	2	1 1/2	1
Center diameter, U-bends.....	4	3	2
Center diameter, coils........	8	6	4
Outside diameter, coils.......	9	7	5

Steel tubing cannot be bent to the absolute limits of copper and brass. Thickness of wall of any tubing must be proportioned to the radius of curvature.

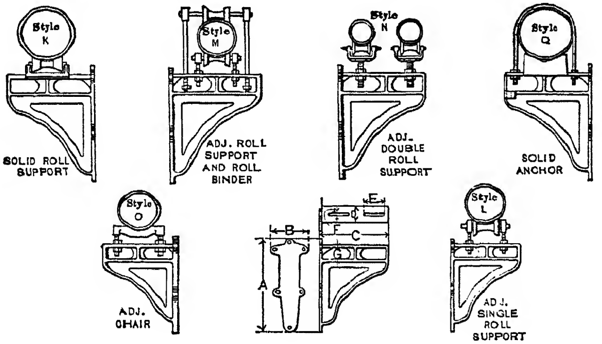

Fig. 47. Pipe Support Brackets

PIPE SUPPORTS.—Pipes may be supported on brackets or suspended from hangers. Figs. 47 to 51, and Tables 58 to 61 show designs and dimensions of brackets and hangers. Pipe on brackets should be carried on rollers formed to the pipe contour to guide its movement, due to expansion, in the desired direction. Long, heavy, suspended pipes, particularly those subjected to high temperature should be spring supported, to avoid the expansion of the pipe lifting the support from its bearing. Spring support is especially desirable for long vertical runs. A form of spring support is shown in Fig. 51.

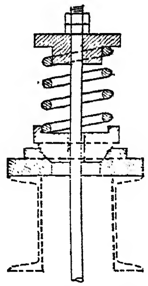

Fig. 51. Spring Support Pipe Hanger

9. STEAM VALVES

Valves for steam lines carrying pressures above 250 lb. per sq. in., but not over 1500 lb., and temperature above 450° F., but not above 750° F., should be of cast or forged steel. For pressures not over 250 lb. per sq. in. and temperatures not over 450° F., they may be of cast or forged steel, cast iron, malleable iron or non-ferrous metal.

Tables 62 to 69 give the dimensions and working pressures of representative valves suitable for steam and boiler feed lines. These tables are much abbreviated and represent but a small portion of the valves that are commercially available. The catalogs of valve manufacturers should be consulted for more detailed information.

Section 6

THE STEAM BOILER

TABLE OF CONTENTS

THE STEAM BOILER *

Steam boilers are of many types, starting, in so far as steaming capacity goes, with small miniature boilers such as are used in tailor shops, and ending with the large boilers used in central power plants. Steam pressures vary from 15 lb. per sq. in. as a maximum for house heating boilers to 1600 lb. per sq. in. and over for central power plants. In special cases forced-circulation boilers are built to operate at pressures up to the maximum at which steam can be generated, *i.e.*, the critical pressure of 3226 lb. per sq. in. In such boilers pressure may be even higher although critical pressure is exceeded.

UNITS OF CAPACITY AND EFFICIENCY

MEASURES FOR COMPARING PERFORMANCE OF BOILERS.—Horsepower. —The term Boiler Horsepower was standard for many years, but is being used to a lesser and lesser extent. It no longer is included in standard codes. A boiler horsepower is the evaporation of 34.5 lb. of water per hour from a temperature of 212° F. into dry saturated steam at the same temperature. This unit never has been used in Europe or for marine boilers built in the U. S.

Builders' Rated Horsepower.—In stationary practice, 10 sq. ft. of heating surface has been considered as equivalent to 1 Boiler Horsepower, based on the evaporation of 3.45 lb. of water per hour from and at 212° F. per sq. ft. of heating surface.

Evaporation.—Water evaporated into steam per square foot of heating surface per hour. Evaporation usually is reduced to equivalent evaporation, *i.e.*, evaporation from water at 212° F. to steam at 212° F.

The *Factor of Evaporation, F*, is the ratio of actual B.t.u. absorption from feed temperature per lb. of steam, whether wet, saturated or superheated, to the latent heat of steam at atmospheric pressure, or 970.2 B.t.u. per lb. $F = (H - h)/970.2$, where H = heat content of 1 lb. of steam, and h = heat content of 1 lb. of feedwater. Equivalent evaporation = (actual evaporation $\times$ factor of evaporation).

Rapidity of Combustion, measured by fuel burned per hour per square foot of grate surface, per cubic foot of furnace volume, or per foot of furnace width.

Efficiency is measured by the ratio (B.t.u. per lb. of fuel absorbed in evaporating and superheating the steam) $\div$ (B.t.u. per lb. of fuel). It will be the same whether based on fuel-as-fired or on dry fuel. In the U. S., efficiency is based on the higher heating value of the fuel. In certain cases, however, it is based on the lower heating value, because the latent heat of moisture, formed by burning the hydrogen in the fuel, is not available to generate steam in a boiler. The lower heating value frequently is used abroad.

With certain fuels, the refuse may contain considerable unconsumed combustible. While the boiler itself cannot be charged with failure to absorb heat not released from the fuel, nevertheless heat represented by unconsumed combustible must be charged against the combined steam-generating unit. Efficiency as ordinarily stated, therefore, is combined efficiency of boiler, superheater, furnace and fuel burning equipment.

A boiler manufacturer guaranteeing performance of a combined unit, including design and operation of elements (stokers, grates, burners, etc.) supplied by others, must require, if efficiency is to have a practical value, certain performance guarantees relative to those elements. Usually such guarantees state maximum or minimum limitations of excess air (or CO_2) and CO in flue gases, and of unconsumed combustibles in ash or refuse, as well as in flue gases.

Factors Affecting Efficiency.—Operation of a steam-generating unit involves the processes of, *a*, converting potential energy of fuel into heat energy, and *b*, transferring this heat energy to a medium (steam) which may be applied to useful purposes. In practice certain characteristic losses of energy occur. The summation of these losses,

---

* The section on Steam Boilers has been revised by the editor-in-chief in collaboration with Dr. D. S. Jacobus and Mr. Robert K. Behr, except where otherwise noted in the text.

in terms of percent of original energy in the fuel, are represented by the difference between the percent efficiency and 100 percent. Unavoidable losses result from the necessity of discharging products of combustion at a temperature above that of the temperature of the fuel and of the air for combustion, and from hydrogen and moisture in the fuel. Avoidable losses, which can be controlled to a certain extent, result from excess air that is heated to temperature of exit gases; from moisture accompanying such excess air; from unconsumed solid combustible in ash and refuse; from unconsumed gaseous combustible in exit gases; and from heat radiated from the setting. Characteristic heat losses in a boiler or steam-generating unit usually are identified as: *

1. Loss Due to Moisture in Fuel.—This loss is due to evaporating moisture in the fuel and superheating it to temperature of the flue gas. Temperature at which evaporation begins may be quite low, due to the low partial pressure of water vapor in gaseous products of combustion. Heat lost is the difference between total heat of water vapor at exit gas temperature and heat of the liquid water at initial temperature, which is taken as fuel temperature. B.t.u. lost per lb. of fuel $= W_m(1090.7 - t_f + 0.455\,T)$ where $W_m =$ lb. of moisture per lb. of fuel; $T =$ temperature of flue gases, deg. F.; $t_f =$ temperature of fuel, deg. F.

2. Loss Due to Water from Combustion of Hydrogen.—Hydrogen in any fuel burns to water, and is discharged with the flue gases as superheated steam. The loss is the difference in the total heat of water vapor at exit temperature and of liquid water at fuel temperature. B.t.u. lost per lb. of fuel $= 9H(1090.7 - t_f + 0.455\,T)$ where $H =$ weight of hydrogen in fuel, lb. per lb. of fuel, other notation as above.

In Europe, latent heat of vapor formed by combustion of hydrogen often is deducted from heating value of the fuel, to obtain the so-called lower heat of combustion. This may result in an increase in efficiency of, say, 3% with a volatile coal, and 6% with oil, over efficiency obtained by using the higher heat value, which is the standard in the U. S.

If, in the ultimate analysis of fuel-as-fired, free moisture is included as hydrogen and oxygen, the above formula will give total moisture loss, and calculation of loss due to free, or surface, moisture as outlined under (1) may be omitted.

3. Loss Due to Moisture in the Air.—This moisture enters the furnace as water vapor. Heat lost is the difference in total heat of water vapor at exit gas temperature and at temperature of air for combustion. Amount of moisture per 1 lb. of air supplied for combustion is determined from wet and dry bulb thermometer readings and the use of a psychrometric chart. B.t.u. lost per lb. of fuel $= w \times m \times 0.47(T - t)$, where $w =$ lb. of dry air supplied per lb. of fuel; $m =$ lb. of moisture per lb. of dry air; $T =$ temperature of flue gases, deg. F.; $t =$ temperature of air surrounding boiler, or re-entering air heater. This loss is small and often is included in unaccounted losses.

4. Loss Due to Dry Chimney Gases is a loss of sensible heat carried by " dry " constituents of flue gases which leave the unit at a temperature higher than that of the surrounding air. B.t.u. lost per lb. of fuel $= 0.24\,W(T - t)$, where $W =$ lb. of dry flue gas per lb. of fuel; $T =$ temperature of flue gases, deg. F.; $t =$ temperature of air surrounding boiler or entering air heater, deg. F. (customarily accepted as datum temperature).

5. Loss Due to Incomplete Combustion of Carbon.—The presence of CO as detected by flue gas analysis indicates incomplete combustion. A small amount is indicative of an appreciable heat loss. B.t.u. lost per lb. of fuel $= (10{,}160 \times C \times CO) \div (CO_2 + CO)$ where $C =$ lb. of carbon burned per lb. of fuel $=$ lb. of carbon per lb. of fuel (from ultimate analysis) minus lb. of combustible in refuse per lb. of fuel; CO_2 and $CO =$ percentages by volume of carbon dioxide and carbon monoxide in the flue gases; $10{,}160 =$ difference in B.t.u. evolved in burning 1 lb. of carbon to CO_2 and to CO.

6. Loss Due to Unconsumed Combustible in Refuse.—Usually, this loss is based on unconsumed combustible matter discharged with furnace ash and refuse. However, for accuracy, the loss due to the unconsumed combustible particles carried into the setting, or up the stack, should be included. The calculation of this loss is quite essential in large boiler units and pulverized fuel installations. B.t.u. lost per lb. of fuel $= 14{,}600(R - A)$, where $14{,}600 =$ the heat value per lb. of carbon (all combustible assumed to be carbon); $R =$ lb. of refuse per lb. of fuel; $A =$ lb. of ash per lb. of fuel (from ultimate analysis).

7. Loss Due to Radiation, Unconsumed Hydrogen and Hydrocarbons, and Unaccounted Losses.—Radiation losses, due to the lack of a satisfactory means of determination, usually are grouped with unaccounted losses, and those due to unconsumed hydrogen and hydrocarbons to form a single item. Loss due to this combined item, in B.t.u. per lb. of fuel, is the difference between B.t.u. per lb. of fuel and the summation of the heat absorbed by the boiler and the six heat losses listed above. A heat balance may be given upon either a dry-fuel or a fuel-as-fired basis. Numerical values in all computations must be consistent with the basis used.

* See also Heat Balance under Rules for Conducting Boiler Tests, A.S.M.E. Power Test Code.

Capacity.—The capacity, or output, of a steam boiler, with or without integral superheater and economizer, may be stated as: 1. Total heat transferred through heating surfaces in B.t.u. per hr. (heat output in steam). 2. Units of evaporation per hour; a unit is 1000 B.t.u. and is called a kilo B.t.u. (*k*B). The mega B.t.u. (*m*B) of 1,000,000 B.t.u. sometimes is used for large installations. (3) Actual evaporation, lb. of steam per hr. at observed steam pressure and quality, or temperature, and observed feedwater temperature. This latter quantity, although useful, does not permit direct comparison of capacities of steam-generating units, because of the extreme range in operating conditions of boiler pressure, quality, superheat and feedwater temperature.

MEASUREMENT OF HEATING SURFACE.—Heating surface of a boiler is all that surface that is in contact with water or steam on one side and with gases or refractory being cooled on the other. Heating surface is measured on the side receiving heat. For details, see Test Code for Steam-Generating Apparatus, p. 16–13. If tubes are covered by blocks, studs, refractories, etc., special rules must be applied, for which no standards as yet (1935) exist.

DESIGN OF STEAM-GENERATING UNITS is largely an economic problem of how to so dispose the total heating surface as to give maximum efficiency at the lowest cost. The economic factors involved in determining the highest practical efficiency are: Load factor; type of load, whether constant or fluctuating; fuel cost; space limitations. Consideration of these factors fixes the desirable final temperature of the gases. The practicability of this temperature depends on the dew-point of the gases. A final temperature at maximum load of at least 50° to 75° F. above the dew-point of the gases is desirable to allow for decreased final gas temperature with decreased loads. With fuels high in sulphur, moisture condensed from the gases will combine with the SO_2 in them and initiate corrosion.

After the lowest practical final temperature of gases at maximum load has been fixed, the most economical disposition of heating surface, as between boiler, economizer and air heater is determined on an economic basis. For instance, the same final temperature may be obtained by using a large air heater and a small economizer, or *vice versa*, and the relative cost of the two arrangements may be the deciding factor.

EFFICIENCY AND PERFORMANCE OF STEAM BOILERS

RELATION BETWEEN BOILER EFFICIENCY AND CAPACITY.—In a well-designed boiler, steaming capacity per sq. ft. of heating surface is limited only by the amount of fuel that can be burned. The amount of heating surface provided for a given evaporation could be much smaller than is customary if other economic factors did not control such reduction in size. Factors limiting high evaporation rates from small surfaces are discussed below.

Efficiency.—Maximum efficiency may occur at a load above or below boiler rated capacity, and may remain practically constant over a considerable range of capacity. Capacity at which maximum efficiency is attained varies with size and type of boiler, type of fuel, method of firing, conditions of operation, etc. With hand-fired boilers, maximum efficiency is at or about boiler rated capacity; with stoker-fired boilers it generally is above normal rated capacity. Large stokers, common in central stations, tend to give maximum efficiency appreciably above boiler rated capacity; however, at low capacities combustion rate is so low that it is difficult to operate with a minimum of excess air.

Economizers tend to keep combined efficiency constant over a considerable range of capacities, due to the fact that at high capacity, increase in economizer efficiency compensates for decrease in boiler efficiency. The most economical load at which a boiler should operate is greater than the capacity which results in maximum combined thermal efficiency.

Gas Friction.—At high capacities, frictional resistance to flow of gases increases rapidly, resulting in an increase in power required to provide draft. In addition there is a probable loss due to a portion of the fuel being carried through the setting and discharged from the stack.

Feedwater must be practically free of ingredients that will cause foaming, priming or scale formation. At high capacities, distilled water may be necessary to avoid these difficulties.

Heat Liberation.—After maximum rate of combustion for any fuel has been established, the only method of increasing capacity is to burn more fuel. The amount is limited by firing equipment and furnace volume.

Maintenance.—At high capacities, cost of maintenance may be excessive, and may offset any gain effected by operating at such capacities.

Cleanliness.—Soot deposited on the tubes will seriously impair efficiency at high capacities, and provision must be made for removal of soot at frequent intervals.

LIMITATIONS OF CAPACITY.—The most important limitation on the steaming capacity of a boiler is the amount of fuel that can be burned in the furnace, the effect of arrangement and extent of heating surface being much less important. This is particularly true of boilers absorbing heat primarily through convection, where maximum evaporation per sq. ft. of heating surface decreases as amount of heating surface per sq. ft. of furnace width increases. The development of water walls, exposed to radiant heat of the furnace, has greatly increased evaporation per sq. ft. of heating surface. Another development, the steaming economizer, also has led to increased evaporation rates. The percent of rated capacity, based on the evaporation of 3.45 lb. of water from and at 212° F. per sq. ft. of heating surface per hr., has increased greatly, particularly in high-capacity units in which the boiler is practically a water screen protecting the superheater.

TYPES OF STEAM BOILERS AND THEIR APPLICATION

Steam boilers may be classified as to construction as water-tube or fire-tube boilers; as to material, as steel or cast-iron boilers; as to service, as power or heating boilers; as to use, as stationary, automotive or marine boilers.

The cylindrical structure, including the ends, of a fire-tube boiler, usually is called the shell. The cylinder superimposed on the tubes of a water-tube boiler is called the steam and water drum. Shells of Scotch-type marine boilers have been built as large as 16 ft. diameter. The largest steam and water drums of water-tube boilers built to date (1935) are 72 in. diameter.

1. WATER-TUBE BOILERS IN CENTRAL STATION SERVICE

ADVANCES IN STEAM BOILER PRACTICE.—Table 1 compares boilers installed in central power plants 30 years ago with present (1935) practice. The increase in pressure and capacity are due largely to the demands of the steam turbine.

The higher steam pressures and steam temperatures in use in 1935, and the higher rates of fuel burning, and consequently increased rates of evaporation, require a correspondingly higher grade of workmanship and the use of special materials, and have removed construction of steam generating equipment from the old-time boiler shop to a high-grade machine shop. The availability for service of large boiler units has become as high as that of the turbine units; the added efficiency has resulted in an advance on the economic side. The efficiency obtained with such large boilers and appurtenances is 85% and over, based on the higher heating value of the fuel. Should the lower heating value be used, efficiency of large generating units would be from 88 to 90%. Steam generating capacity has increased as well as efficiency, and boiler units with a single furnace have been built to evaporate 1,000,000 lb. of water into steam per hour as compared to about $^1/_3$ of this amount 10 or 15 years ago. Furnace design has formed an important part of the development. Water-cooled furnace walls and improved methods of burning fuel make it possible to operate for long periods of time without shut-down caused by furnace difficulties.

Fig. 1 shows a typical installation of a large central power plant boiler with 7214 sq. ft. of heating surface, 12,900 sq. ft. of superheater surface, a maximum evaporative capacity of 275,000 lb. of steam per hr. and built for a working pressure of 1400 lb. per sq. in. The furnace is water cooled, being arranged with Bailey blocks to form Bailey furnace walls (see p. 6–93). The boiler is fired with pulverized coal inter-tube burners, and has a Bailey water-cooled slag-tap furnace. Temperature of steam from the primary superheater is maintained at, substantially, 750° F. by passing a portion of it through a de-superheater at the higher loads, and returning heat from the steam to the boiler. Steam from an intermediate stage of the steam turbine passes to a reheater in the boiler setting. This,

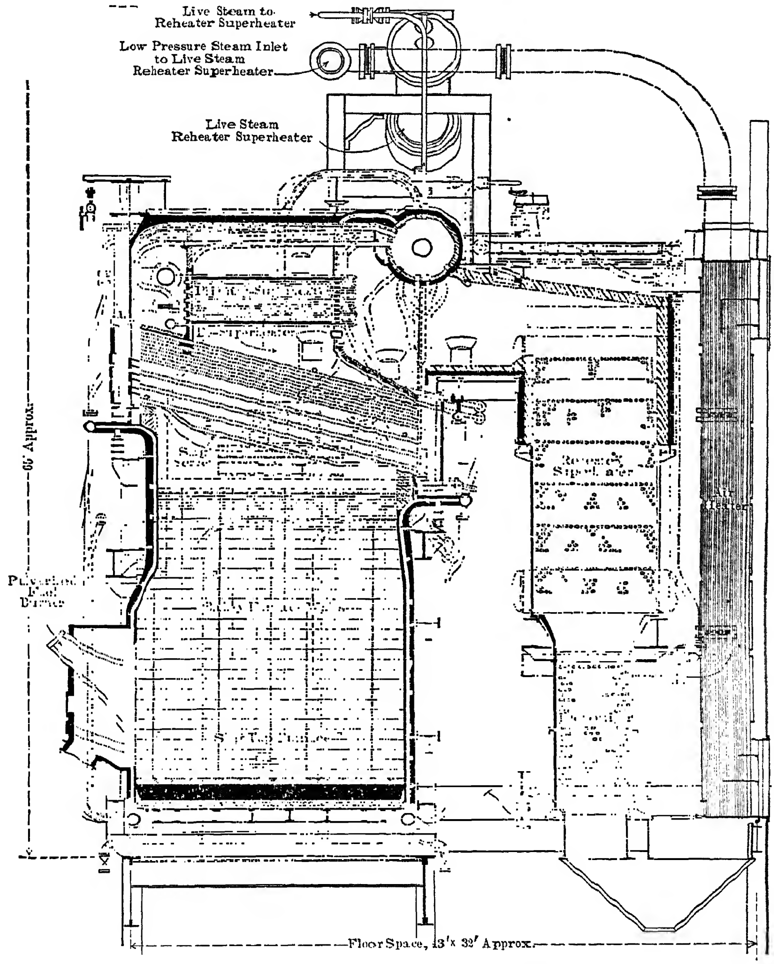
Table 1.—Comparison of Central Power Plant Boilers in 1905 and 1935

	1905	1935
Heating surface, largest unit	6,040	53,926
Heating surface, boiler, superheater, economizer and air heater, sq. ft.	7,000	144,402
Working pressure, lb. per sq. in.	225	650 to 1,600
Temperature superheated steam, deg. F. max.	550	700 to 900
Maximum rate of evaporation, lb. per hr. per boiler unit	30,000	1,000,000
Volume of boiler setting for largest boilers, cu. ft.	7,650	42,255*
Height, bottom of walls of setting to center of steam and water drum for largest boilers, ft.	19	78

* Includes two boilers set over a single furnace.

together with a live steam reheater, maintains a total temperature of superheated steam of about 750° F. irrespective of varying temperature of steam leaving the turbine. To accomplish this, steam from an intermediate stage of the turbine first passes through a live-steam reheater and then through the reheater in the boiler setting, where it is heated by the combustion gases.

The boiler unit is 65 ft. high measured from top of foundations. Area of the base is 1375 sq. ft. The tubes of boiler, superheater, de-superheater, live steam reheater, reheaters using gases as the heating medium, economizer, air heater and furnace placed end to end would extend approximately 23 miles. To drive the induced and forced blast fans requires a maximum of 400 Hp.; the feed pump requires 650 Hp. A special semi-manual apparatus controls combustion. Units of this type are in a class by themselves,



, 1. Central Station Boiler with Superheater Reheater, De-superheater and Economizer

and involve elements far beyond those that had to be considered in building smaller boilers in the old-time boiler shop.

Some engineers prefer to use, say, 900 lb. pressure and about 900° F. temperature of superheated steam, with no reheater to reheat steam between turbine stages. Others prefer 1400 lb. pressure with, say, 1200 lb. at the turbine throttle. In earlier practice, this would require using a reheater to avoid undue moisture in the low-pressure stages of the turbines. Even with a turbine operating at 1200 lb. steam pressure, present tendency is to heat the steam high enough to make a reheater unnecessary. As pressures increase, the use of a forced circulation or series type boiler instead of a natural circulation boiler may become advisable for certain types of work.

2. WATER-TUBE BOILERS FOR INDUSTRIAL USE

Water-tube boilers for industrial use are shown in Figs. 2, 3 and 4.

Fig. 2 shows a Stirling boiler with a chain grate stoker, a water-cooled furnace, an economizer and an air heater. Fig. 3 shows a Babcock & Wilcox boiler with a superheater between the first and second passes, equipped with an air heater, an underfeed stoker, and water walls in the furnace. A slag screen consisting of tubes spaced at double the distance apart of the tubes of the first bank, placed where the hot gases first impinge on the boiler, cools the gases and the contained particles of molten slag to a point where the slag will not adhere to the more closely spaced tubes. The double spacing is obtained

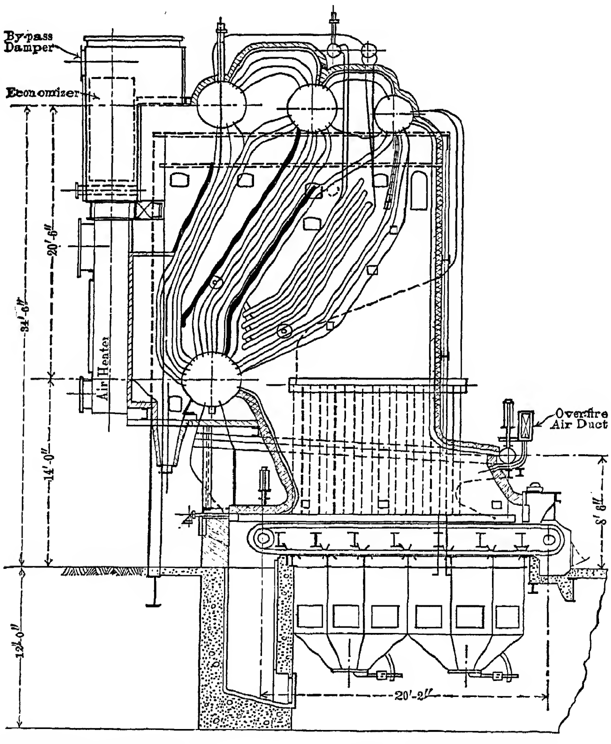


FIG. 2. Stirling Boiler and Chain Grate Stoker, Slag Screen, Water-cooled Furnace, Economizer and Air Heater

by bending outward alternate tubes in the front row. The superheater is placed back of the first bank of tubes.

Some engineers prefer straight-tube boilers, such as the Babcock & Wilcox boiler shown in Fig. 3, while others prefer to use bent-tube boilers similar to the Stirling. No rule can be given as to the best design of boiler for general use. Every case must be considered individually.

Fig. 4 shows a boiler with an integral water-tube furnace, particularly adaptable to burning pulverized coal, oil or gas. These boilers have been designed to evaporate from 4000 to 175,000 lb. of steam per hour. The gases make three horizontal passes through the boiler, giving a high efficiency with minimum draft drop.

The foregoing boilers all are fitted with superheaters, which is common practice for power boilers. For process work, where constant temperature is required, superheaters are omitted.

Waste Heat Boilers

Waste heat is sensible heat in gases discharged, usually from some high-temperature process, as a heating furnace. A number of Babcock & Wilcox and Stirling boilers, as

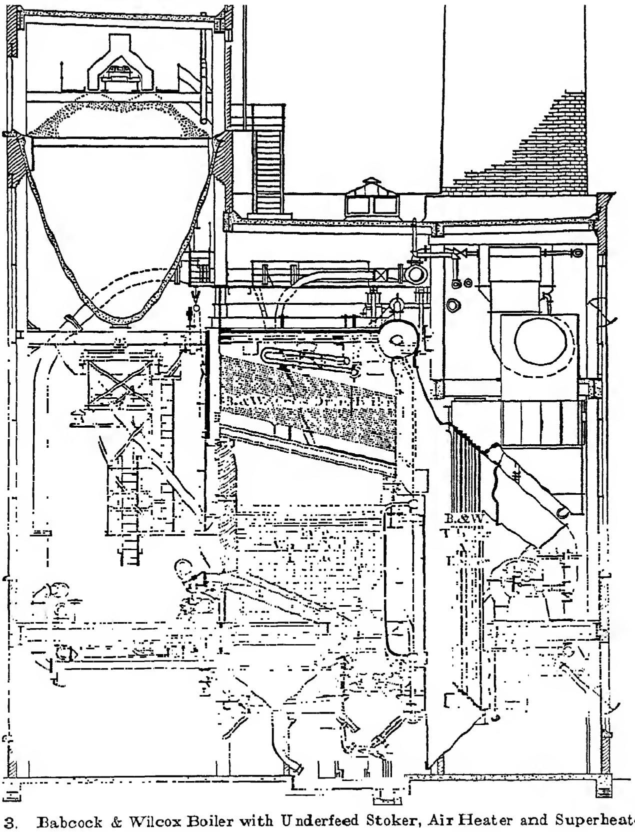

Fig. 3. Babcock & Wilcox Boiler with Underfeed Stoker, Air Heater and Superheater

shown in Figs. 2 and 3, have been used as waste heat boilers. Stirling boilers have been used in the smelter industry, with baffles removed, or arranged to give minimum draft drop, so that the high stacks used would provide enough draft to operate the smelting furnaces and draw waste gases through the boilers. In later practice, as in waste heat boilers for open hearth furnaces, a higher velocity of gases over the tubes was found to be of advantage. This involves a higher draft loss through the boiler and necessitates using induced draft fans. Special types of boilers, Figs 5 and 6, were later developed.

In the arrangement shown in Fig. 5 the gases pass longitudinally over vertical tubes. In Fig. 6 they pass in a generally horizontal direction through the tubes of a fire-tube boiler.

3. BOILERS USING BLAST-FURNACE GAS

Earlier steel mill power plants comprised a number of small boiler units, some designed for using blast-furnace gas exclusively, others being fired with coal on stokers to supplement the gas-fired units, and to carry the entire load when the gas went off. Pulverized coal firing and improvement in gas burners and furnace design and construction has

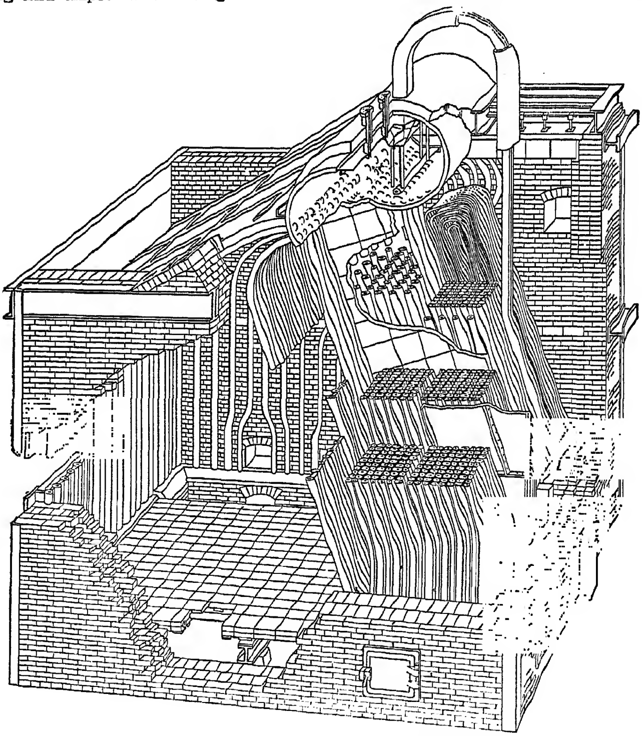

Fig. 4. Boiler with Integral Water-tube Furnace

made possible the firing of blast furnace gas and of coal in the same furnace. This decreases capital investment in plant for a given power requirement, and results in more complete and efficient use of available gas supply.

BURNER DESIGN.—The efficiency of blast-furnace gas burners is due primarily to methods of breaking the gas into thin streams and so introducing air for combustion as

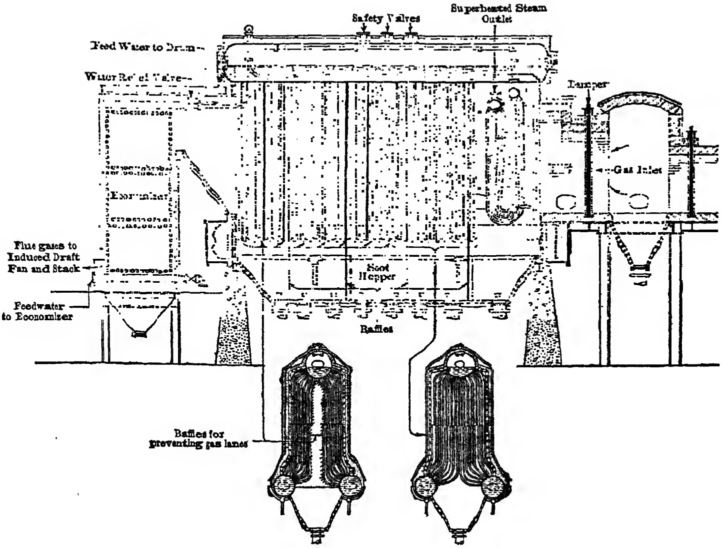

FIG. 5. Three-drum, Vertical-tube Waste Heat Boiler

to insure thorough mixture before ignition. Originally, aspirating burners were used, but the trend is toward a design in which both gases and air for combustion are brought to the burner under pressure. The air supply can be adjusted for varying gas conditions, and can be maintained at a minimum regardless of gas pressure in the main. Blast-furnace gas may be burned with as little as 15% excess air, instead of 100% excess air required in early box-type burners. Systems of automatic control permit speeds of induced and forced draft fans to be regulated by pressure in the gas main. Fig. 7 is a plan of a Babcock & Wilcox cross-tube blast-furnace gas burner.

FURNACE AND BOILER DESIGN.—Because of its low calorific value, blast-furnace gas burns slowly. Temperatures attained in the furnace are much lower than with other common fuels. Relatively large furnace volumes are required to insure complete burning before gases enter the tube bank, and when firing blast-furnace gas alone, no water-cooling

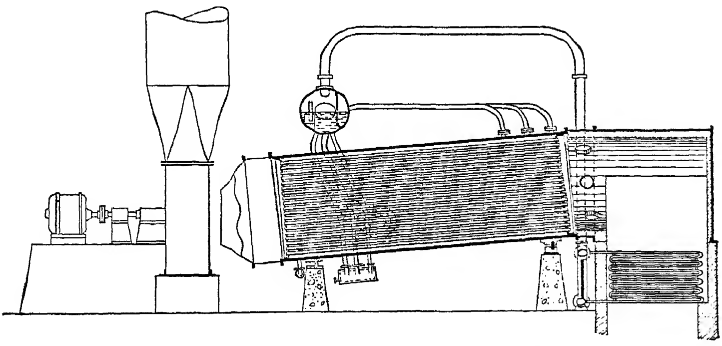

FIG. 6. Horizontal Fire-tube Waste Heat Boiler

other than that of the boiler is required in furnaces. When pulverized coal is fired in combination with gas, or is fired in the same furnace with " gas off ", water-cooled wall construction is necessary in certain zones to prevent destruction of brickwork and to facilitate removal of ash. Present practice (1935) indicates furnace volumes of 50 to 60 cu. ft. per million B.t.u. released per hr., compared with 30 to 40 cu. ft. in early installations. Water cooling of rear wall and hopper floor is customary, although the extent of such water-cooled surfaces should be governed by anticipated loads and ratios of firing gas and auxiliary fuel. Preheated air and the turbulence given by well-designed burners produce an appreciably shorter flame than heretofore obtained.

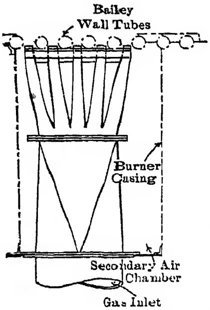

FIG. 7. Burner for Blast-furnace Gas

Since high furnace temperatures are favorable to high overall rates of heat absorption it is necessary to offset the lower furnace temperature obtained with blast-furnace gas if efficiencies are to be comparable to those of boilers fired with other fuels. Heat absorbed from direct radiation in a blast-furnace gas-fired boiler is about 40% of that absorbed in a similar stoker-fired boiler. If total absorption is to be comparable in both cases, absorption by convection must be increased in the boiler fired by blast-furnace gas. As in waste heat practice, high gas velocities will result in high rates of heat transfer by convection. High gas velocities are inherent in boilers fired with blast-furnace gas, since even with best combustion conditions, products of combustion weigh approximately 70 lb. per developed horsepower, as compared to about 45 lb. in stoker-fired boilers. Gas velocity may be further increased by decreasing the ratio (gas passage area through boiler ÷ boiler heating surface). The high gas velocity develops high frictional resistance, which usually necessitates using induced draft fans.

ECONOMIZERS USED WITH BLAST-FURNACE GAS BOILERS.—Despite low exit gas temperatures from boilers fired with blast-furnace gas, economizers, when installed, have less heating surface than those in stoker-fired practice. This is due to the fact that high gas velocity gives a high ratio of gas weight to weight of water in the economizer. The resultant heat transfer rates are sufficiently higher than those in stoker-fired practice to attain a given feed-water temperature with a smaller amount of economizer surface.

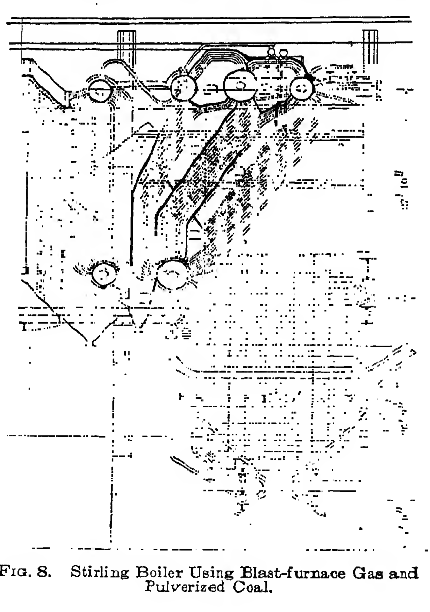

FIG. 8. Stirling Boiler Using Blast-furnace Gas and Pulverized Coal.

TYPICAL BOILERS.—A typical installation (1928) consisted of 1460 Hp. Stirling boilers equipped with superheaters, economizers, air heaters, air-cooled side walls, water-cooled hopper floors and bare tubes protecting the front wall. Units are fired both with blast-furnace gas and pulverized coal. At working pressures of 375 lb. per sq. in. and capacities of 175,000 lb. of steam per hr., overall efficiency has been about 83%. Draft loss through the unit was 7.7 in. of water. A unit installed in the same plant in 1932 (see Fig. 8) shows the trend toward higher capacities. The unit was designed for a capacity of 200,000 lb. of steam per hr., efficiency of 85%, and draft loss of 6.8 in. when burning blast-furnace gas, and a capacity of 300,000 lb. of steam per hr., efficiency of over 86% and draft loss of 6.7 in. when burning pulverized coal. In this unit refractory-faced water-cooled side walls have been added to permit operation at the higher rates with pulverized coal.

4. FIRE-TUBE AND SMALL WATER-TUBE BOILERS

HORIZONTAL RETURN TUBULAR BOILERS are used widely for small heating plants where working pressures ordinarily do not exceed 125 or 150 lb. per sq. in. In certain instances, they are built for considerably higher pressures. Fig. 9 shows a typical arrangement of a hand-fired horizontal return tubular boiler. This is the standard setting recommended by the Hartford Steam Boiler Inspection and Insurance Co.

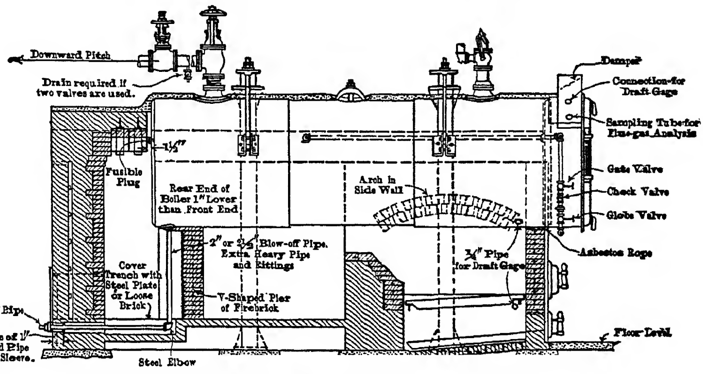

Fig. 9. Setting of Horizontal Return Tubular Boiler

The arrangement of tubes in horizontal return tubular boilers varies. Typical arrangements are shown in Fig. 10. The usual sizes of boilers and the heating surface available with different arrangement of tubes are given in Table 1. Weights of boilers are given in

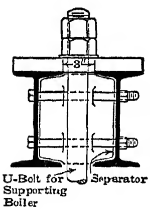

Fig. 11. I-Beam Suspension for Horizontal Tubular Boilers

water given in Table 2 are for average cases and are based on a weight of water of 62.5 lb. per cu. ft.

Suspension of Horizontal Tubular Boilers.—Horizontal tubular boilers are suspended from pairs of I-beams, as shown in Fig. 9, carried on columns. Round or square cast-iron columns or built-up plate-and-angle columns sometimes are used, but present practice uses the H-section as a column. Table 3 shows the sizes and weights of I-beams and H-sections recommended for various sizes of boilers. The size of I-beams is based on a fiber stress of 12,500 lb. per sq. in. The beams should be bolted together in pairs as shown in Fig. 11. The maximum ratio of slenderness of columns (l/r) has been taken as 120. Table 3 gives a heavier column than would be given by the standard tables of structural sections, since the stresses in boiler columns are not balanced nor distributed equally. The maximum length of column given in Table 3 should not be exceeded. The table assumes that the col-

The I-beam section is not recommended as a boiler column, because its shape is not well adapted to use as a column. Data on built-up plate-and-angle columns and on round and square cast-iron columns are given in the *Boiler Book* of the Hartford Steam Boiler Inspection and Insurance Co., Hartford, Conn.

For other details of construction of horizontal return tubular boilers, including dimensions of boiler tubes, braces, stays, etc., see Boiler Construction, pp. 6–18 to 6–42.

For low-pressure horizontal return tubular boilers, see p. 11–11.

SMALL WATER-TUBE BOILERS.—Fig. 12 shows a small water-tube boiler fired with a chain grate stoker. The smaller sizes of these boilers are shipped after being

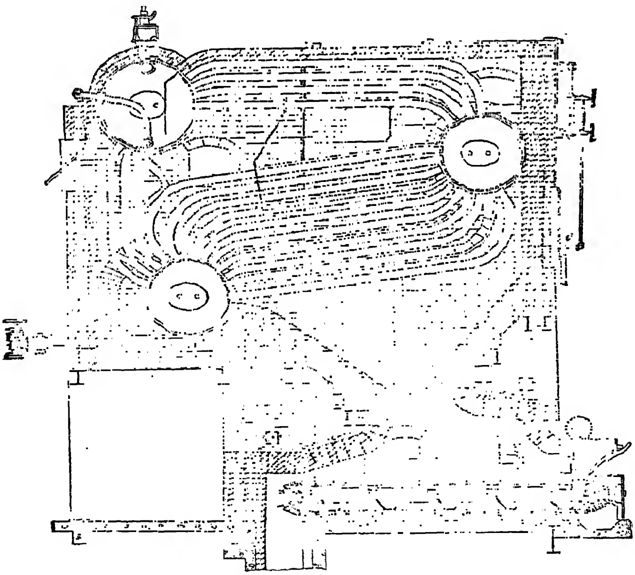

Fig. 12. Stirling Boiler with Babcock & Wilcox Stoker

completely assembled in the shop. The boiler may be provided with a superheater if desired.

BOILERS FOR MISCELLANEOUS SERVICES are discussed elsewhere. See Railroad Engineering, Heating and Ventilation, Marine Engineering.

5. BOILERS WITHOUT NATURAL CIRCULATION

TYPES OF FORCED CIRCULATION BOILERS.—These boilers are of two types: 1. Water and steam flow directly through the boiler and superheater respectively, termed a once-through boiler. 2. More water is fed to the boiler than is evaporated. The mixture of steam and water passes to a chamber where water is separated from the steam before the steam passes through the superheater. In Type 2, water may be more readily treated for preventing corrosion of the interior of boiler tubes than in Type 1. In Type 2 boilers, any ingredient added to prevent corrosion is removed with the excess water which is separated from the steam, while in Type 1 boilers, such ingredients pass from the boiler with the steam and may give trouble by being deposited in the turbine.

OPERATION OF FORCED CIRCULATION BOILERS.—In operating forced circulation boilers, it is most important that a proper control device be employed. Natural circulation boilers have an appreciable storage of water at the saturated temperature corresponding to the pressure, which assists in maintaining steady steam pressure. In a series boiler there is little contained water as compared with a natural circulation boiler. This makes it necessary to use a quickly responsive control system to regulate combustion and feedwater supply. The difficulty of operating a forced circulation boiler at varying loads has hindered its use. This difficulty no longer exists, as a successful automatic control has been developed for use with this type boiler.

A once-through series boiler installed at Purdue University for operating at pressures up to the critical pressure of about 3200 lb. and over is shown in Fig. 13. It has a Bailey automatic control which regulates fuel, feedwater and air supply.

6. PERFORMANCE OF STEAM BOILERS

The performance of a steam boiler comprises both its capacity for generating steam and its economy of fuel. According to the A.S.M.E. Power Test Code the performance of a boiler (including firing equipment) should be expressed in terms of: 1. Efficiency, *i.e.*, ratio of heat units output to high calorific value of the fuel (dry, or as-fired). 2. Fuel (dry, or as-fired), lb. per hr. per sq. ft. of grate surface, per retort, or per burner. 3. Combustion space, cu. ft. per lb. of fuel (dry, or as-fired) per hr. 4. Rate of heat absorption per sq. ft. of steam-generating unit surface per hour, units of evaporation. 5. Heat released, B.t.u. per cu. ft. of furnace volume per hr.

Efficiency usually determined is that of the steam-generating unit, and is the overall efficiency of boiler, superheater, economizer, reheater, air heater, furnace, and fuel-burning equipment. The terms superheater, economizer, reheater, and air heater are omitted if the unit does not include these appurtenances. If air heaters are installed, a comparative efficiency also is calculated. In determining this efficiency, heat absorbed by air heater is not prorated over the steam-generating surface (boiler, superheater, economizer and reheater). Hence, comparative efficiency is lower than overall efficiency by an amount equal to percentage of heat absorbed by air heater (B.t.u. absorbed by air heater per lb. of fuel $\times$ 100 $\div$ High calorific value of fuel, B.t.u. per lb.) In many instances, regardless of the various types of heat-absorbing surfaces installed, efficiency of boiler and furnace, or boiler, superheater and furnace also is determined.

OVERALL EFFICIENCY OF A STEAM-GENERATING UNIT varies principally with type of fuel, methods of firing, and various combinations of heat absorbing surfaces. Overall efficiencies of 85% or more have been achieved in several instances without economizers or air heaters, but for continuous operation such performances cannot be expected. Yearly overall efficiencies of 80% have been reported for large central stations, but the average is lower, probably about 77%. In large isolated or industrial plants, a yearly overall efficiency of 70% is a fair average. Small isolated or industrial plants, in most instances, average considerably less, although a number of such plants fired by pulverized fuel or oil, have reported yearly overall efficiencies of 70% or more.

Several installations consisting of boilers, superheaters, economizers, reheaters, water-cooled furnaces, and air heaters, or some combination thereof, have reported overall test efficiencies of 86–90% when fired by pulverized fuel, mechanically atomized oil, underfeed or chain-grate stokers, and 82–86% when fired by natural gas. Overall test efficiencies as high as 94% have been obtained, and yearly overall efficiencies of 86% are common. A pulverized fuel installation, consisting of boiler, superheater, economizer, and water-cooled furnace reports a monthly efficiency of 88%, while another pulverized fuel installa-

tion, consisting of a high-pressure boiler, superheater, economizer, reheater, water walls and air heater reports a monthly operating efficiency of 89.1%, and a 6-month combined operating efficiency of 87.6%. High monthly, or yearly operating efficiencies depend on load characteristics, type of fuel, and the most modern equipment and operating methods.

EVAPORATION RATES.—A steam-generating unit of total water heating surface of 16,763 sq. ft., consisting of boiler 5938 sq. ft., furnace water walls and floor 2460 sq. ft., and steaming economizer 8365 sq. ft., has operated at a capacity of over 290,000 lb. per hr. This corresponds to an equivalent evaporation, from and at 212° F., of over 368,000 lb. per hr., or 43.9 lb. per sq. ft. of heating surface per hr., or approximately 1275% of rated capacity, when based on heating surface of boiler and furnace water walls and floor. Based on total water heating surface, including economizer, evaporation is 22 lb. per sq. ft. of heating surface per hr., or approximately 640% of rated capacity.

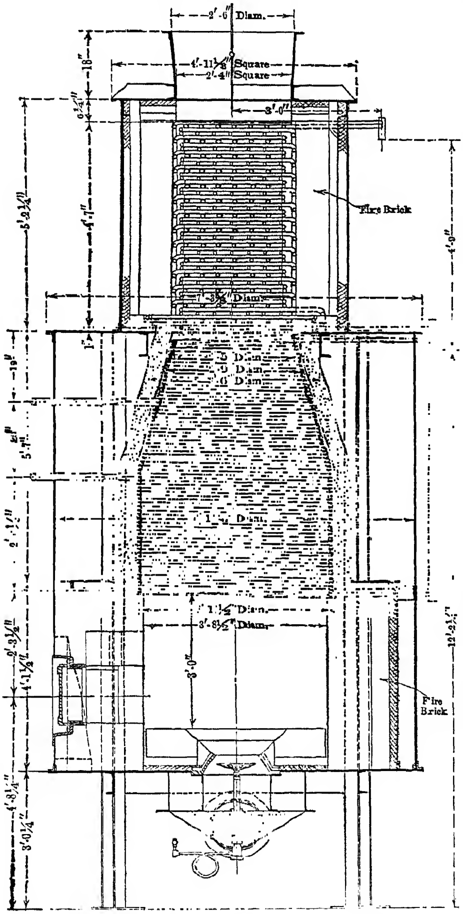

Fig. 13. Continuous Circulation Boiler

Water-tube Boilers.—Maximum rates of evaporation per sq. ft. of heating surface, from and at 212° F., of a horizontal water-tube boiler, absorbing heat mostly through convection, are from 15.1 lb. per hr. for a boiler 18 tubes high, to 22.5 lb. per hr. for a boiler 11 tubes high. Evaporation rates exceeding 20 lb. per sq. ft. of heating surface per hr., from and at 212° F., have been obtained with inclined tube multi-drum boilers.

Horizontal Return Tubular Boilers.—Evaporation rates of 3.5 to 5.5 lb. per hr. from and at 212° F. are most common for horizontal return tubular boilers used in small stationary plants. Locomotive boilers rarely exceed 16 lb. per sq. ft. per hr., but such rates are very uneconomical, because of steam required for creating draft and the attendant loss of coal up the stack.

Marine Boilers.—A standard Babcock & Wilcox marine boiler at the U. S. Naval Oil Testing Plant, Philadelphia, has operated at a maximum evaporation rate of 18.7 lb., from and at 212° F., per sq. ft. of heating surface per hr., while from a Babcock & Wilcox express type marine boiler, installed at the same plant, a maximum evaporation of 22.7 lb., from and at 212° F., per sq. ft. of heating surface per hr. was obtained. Furnace arrangement and volume were those common in marine practice.

HEAT TRANSFER in B.t.u. per hr. per sq. ft. of heating surface differs widely in different boilers and in different sections of the heating surface of any boiler. In the design of boilers actual heat transfer per sq. ft. of each type of heating surface must be known, as well as the variables affecting such transfer. Experiments have shown that the lower row of tubes between the first baffle and the front header of a Babcock & Wilcox boiler, with uncooled furnace, absorbs heat at an average rate per sq. ft. of heating surface

equivalent to the evaporation of from 50–75 lb. of water from and at 212° F. No distinction was made as to the amount of heat absorbed by radiation and by actual contact between hot gases and tubes, but a large portion of the heat absorbed was by direct radiation.

In a Babcock & Wilcox boiler with ordinary clean surfaces, if W = total weight of gases passing per hr., lb., and A = average gas passage area, sq. ft., of all passes of the boiler, average heat transfer U, B.t.u. per sq. ft. per hr. per deg. F. mean temperature difference may be closely approximated by $U = 2 + 0.0014(W/A)$.

A paper by C. F. Hirshfeld and G. U. Moran (*Trans.* A.S.M.E. FSP–52–34) gives a record of performance of 186 large steam-generating units in over 60 power stations in all sections of the U. S., under widely different conditions of operation, and with different classes of fuel. Many data relative to heat release and heat transfer are included.

BOILER CONSTRUCTION

1. SCOPE OF CODES FOR CONSTRUCTION

The Code most largely used for construction of land boilers is the Boiler Construction Code of the American Society of Mechanical Engineers. The Code of Boiler Rules of the Commonwealth of Massachusetts was developed before that of the A.S.M.E. The state of Ohio also developed its own code. These codes are coming closer and closer together, and there is a growing desire to make the fundamental features the same in all.

Rules covering construction of steam boilers for marine service have been issued by U. S. Department of Commerce, Bureau of Navigation and Steamboat Inspection, under the title Amended Rules I and II, General Rules and Regulations, 51st Supplement to General Rules and Regulations, January 1, 1935. Existing codes and regulations were considered in formulating these rules, including the A.S.M.E. Boiler Code. Rules for fusion welded drums or shells of marine boilers and pressure vessels are included, being based on those prepared by a subcommittee of the Committee on Welding in Marine Construction of the Am. Welding Soc., which, in turn, were based on those prepared by the A.S.M.E. Boiler Code Committee in co-operation with the Am. Welding Society.

The A.S.M.E. co-operated with the Am. Petroleum Inst. in preparing a Code for Construction of Unfired Pressure Vessels for Petroleum Liquids and Gases, the first edition of which, designated as A.P.I.–A.S.M.E. Code, was published in 1934.

FACTORS OF SAFETY USED IN VARIOUS CODES.—No term has been misused so widely as the so-called factor of safety. Consider the following three types of vessels, designated as types A, B and C.

Type A. Steam Boilers or Vessels Pierced with Unreinforced Holes.—In these vessels, stress at the edge of holes may be over twice average hoop stress. In applying an initial hydrostatic test of ($1\,{}^1/_2 \times$ working pressure) to a drum built with a so-called factor of safety of 5, the steel at the most highly stressed part will be so strained as to produce a permanent set and redistribution of forces in the stressed area. The factor is based on ultimate strength, and with a steel in which yield strength is $^1/_2$ the ultimate strength, yield strength would be $2\,{}^1/_2$ times average hoop stress at the working pressure. If stress at the sides of tube holes is ($2 \times$ average hoop stress), and the hydrostatic test is made at ($1\,{}^1/_2 \times$ working pressure), stresses at the sides of tube holes would be ($3 \times$ average hoop stress) at the working pressure. This would exceed yield strength of the material. If the so-called factor of safety is made less than 5, as is often done, there is a greater yielding of the material on application of the hydrostatic test and a greater redistribution of stresses.

Type B. Vessels Having No Holes or Other Stress Raisers in Their Shells.—In these vessels, yield strength would not be exceeded until hoop stress, which would be uniform from end to end of cylinder, was exceeded. Such vessels could be operated safely with a much lower so-called factor of safety than those with holes or other stress raisers in the shell. Application of a hydrostatic test of ($1\,{}^1/_2 \times$ working pressure) to a vessel of this type, built with a factor of safety of 5, would not exceed yield strength, as would occur with Type A vessels with unreinforced holes or other stress raisers in their shells.

Type C. Vessels of Type of Construction Used for Penstocks for Boulder Dam.—This construction is described by C. M. Day and Peter Bier of the U. S. Bureau of Reclamation in *Mech. Engg.*, Aug., 1934. The yield strength of the special steel used in the penstocks is 38,000 lb. per sq. in.; hoop stress was limited to 18,000 lb. per sq. in. The

article describes tests made by elastic analysis, and by subjecting 1/6 scale models of the penstocks to hydrostatic pressure. The parts were so built that maximum stress at any point would not exceed about 19,000 lb. per sq. in.

Each of the three types of vessels has its own field of application. Type A includes all pressure vessels having unreinforced holes, or in which unreinforced holes, as telltale holes for determining shell thickness, may be drilled after the vessels are in operation. This type is covered by A.S.M.E. and similar construction codes.

Type B includes vessels constructed under rules of the Interstate Commerce Commission for transporting liquids and gases under pressure. For such vessels, a so-called factor of safety of, say, 3 1/2 where there is no corrosion, will give as great a degree of safety as some Type A vessels where the factor is 5.

Type C represents the highest type of construction for pressure vessels where walls cannot be made of uniform thickness with no stress raisers. By limiting both hoop and maximum stresses, due to departing from uniform shell thickness, as well as at special branch connections and reinforced openings, no question can arise as to the effect of exceeding yield strength in any part of the structure.

THE A.S.M.E. CODE FOR LOCOMOTIVE BOILERS specifies:—

Factor of safety used in design and construction of new boilers shall not be less than 4.5.

Factor of safety used in determining maximum allowable working pressure calculated on conditions actually obtained in service shall not be less than 4.0.

Maximum allowable working pressure determined by conditions obtained in service shall not exceed that for which boiler was designed.

THE JOINT A.P.I.–A.S.M.E. CODE contains provisions for removing vessels from service if the factor of safety becomes lower than certain set figures. At a first glance it would appear that factors of safety given in the A.P.I.–A.S.M.E. Code are lower than those given in the Unfired Pressure Vessel Section of the A.S.M.E. Boiler Code in the ratio of 4 to 5, whereas the factor of 4 applies to a figure below which vessels cannot be operated, and the A.S.M.E. Code refers to initial factor of safety when boilers are built. Another feature in the two codes brings the two factors for stress-relieved unfired pressure vessels nearer together. In the A.P.I.-A.S.M.E. Code, tensile strength used in applying the formulas is that for coupons which are tested at the steel mill, after being stress-relieved in the same manner as the vessel will be stress-relieved; whereas in the A.S.M.E. Code coupons for such vessels are not stress-relieved at the steel mill. In stress-relieving the coupons, which is done by holding them at a temperature of from 1100 to 1200° F., for 1 hour per inch of thickness of plates, tensile strength may be lowered about 10%. The factor 5 in the A.S.M.E. Code was considered ample to cover this lowering of the tensile strength; whereas in the A.P.I.–A.S.M.E. Code it was embodied in the Code on account of the lower operating factor.

RULES FOR CONSTRUCTION.—The matter which follows will be limited to the rules of the A.S.M.E. Boiler Code which, as already stated, includes rules for the construction of unfired pressure vessels.

The A.S.M.E. Boiler Construction Code has received wide recognition and has been enacted into the laws of the following: Arkansas, California, Delaware, Indiana, Maryland, Michigan, Minnesota, Missouri, New Jersey, New York, Ohio, Oklahoma, Oregon, Pennsylvania, Rhode Island, Utah, Washington, Wisconsin, District of Columbia, Hawaii, Canal Zone. It has also been adopted by the cities of: Chicago, Ill.; Detroit, Mich.; Erie, Pa.; Evanston, Ill.; Houston, Tex.; Kansas City, Mo.; Los Angeles, Cal.; Memphis, Tenn.; Nashville, Tenn.; Omaha, Neb.; Parkersburg, W. Va.; Philadelphia, Pa.; Scranton, Pa.; Seattle, Wash.; St. Joseph, Mo.; St. Louis, Mo.; Tampa, Fla.

In the U. S., boilers for merchant vessels must be constructed according to rules and regulations prescribed by the Bureau of Navigation and Steamboat Inspection. Boilers for British merchant vessels must be constructed in accordance with rules of the British Board of Trade.

The following rules are greatly condensed from the A.S.M.E. Boiler Construction Code, edition of 1933, with revisions to 1935. *The Code itself should be consulted in actual design*, as a number of important features have been omitted. When fabricating boilers to be operated in states and municipalities having their own laws and ordinances, reference should be made to these as well.

The following abstract relates to power boilers only. The sections of the code relating to locomotive boilers, low-pressure heating boilers, miniature boilers and unfired pressure vessels are issued as separate publications and reference should be made to them in the design and construction of any apparatus in the foregoing classifications.

Piping systems in connection with steam boilers, especially those conveying high-temperature high-pressure steam, should be constructed in accordance with the American Standard Piping Code. An abstract of this code is given on pp. 5–23 to 5–30.

2. MATERIALS USED IN BOILERS

MATERIAL SPECIFICATIONS (A.S.M.E. Code).—Specifications for certain of the materials used in various parts of boilers are given in Table 1 and the notes appended thereto. See the Code for specifications of the following materials not listed in Table 1.

Steel Plates of Flange and Firebox Qualities for Forge Welding	A–89
Forged or Rolled Steel Pipe Flanges for High-temperature Service	A–105
Alloy Steel Bolting Material for High-temperature Service	A–96
Carbon Steel and Alloy Steel Forgings	A–18
Welded and Seamless Steel Pipe	A–53
Welded Wrought-iron Pipe	A–72
Copper Plates	B–11
Copper Bars for Staybolts	B–12
Seamless Copper Boiler Tubes	B–13
Copper Pipe	B–42
Brass Pipe	B–43
Open-hearth Iron Plate of Flange Quality	A–129

In the above list, and in Table 1, the corresponding A.S.T.M. specification is given when available.

Steel plates for any part of a boiler exposed to fire or products of combustion and under pressure shall be of the quality of steel designated as Firebox steel. Where firebox quality is not specified, when under pressure, steel shall be of firebox or flange quality, as designated in the specifications. Braces when welded shall be of wrought iron of the quality designated Extra Refined Bar Iron. Manhole and handhole covers and other parts subjected to pressure, also braces and lugs made of steel plate, shall be of firebox or flange quality. Steel bars for braces and other boiler parts, unless otherwise specified, shall be of a quality designated Steel Bars. Staybolts are to be of iron or steel, designated as Staybolt Iron or Staybolt Steel. Rivets shall be of steel or iron of the quality designated Boiler Rivet Steel or Boiler Rivet Iron.

Cross pipes connecting steam and water drums of water-tube boilers, headers, cross-boxes and all pressure parts of the boiler proper, over 2 in. pipe size or equivalent cross-sectional area, shall be of Wrought Steel or of Grade B cast steel designated in the specifications for steel castings, when maximum allowable pressure exceeds 160 lb. per sq. in. Malleable iron also may be used if maximum allowable pressure does not exceed 350 lb. per sq. in., if form and size of the internal cross-section, perpendicular to the longest dimension of the box, will fall in a 7 × 7 in. rectangle.

Mud drums of boilers used other than for heating purposes, shall be of wrought steel or Grade B steel casting. Pressure parts of superheaters, separately fired or attached to stationary boilers, unless of the locomotive type, shall be of wrought steel, Grade B cast steel, or puddled or knobbled charcoal wrought iron.

Cast iron shall not be used for nozzles or flanges attached directly to the boiler for any pressure or temperature, nor for boiler or superheater mountings such as connecting pipes, fittings, valves, etc., for steam temperatures of over 450° F., or pressures of over 250 lb. per sq. in.

Water-leg or door-frame rings of vertical fire-tube boilers and of locomotive and other type boilers, shall be of wrought iron or steel or cast steel (Class A or Class B). The O. G. or other flanged construction may be used as a substitute in any case.

Quench Bend Test.—The test specimen when heated to a light cherry red, not less than 1200° F., and quenched at once in water whose temperature is between 80° and 90° F. shall bend through 180° flat on itself without fracture on outside of bent portion. Applicable to boiler rivet steel and staybolt iron, excepting that the iron must be heated to yellow heat.

Notes to Table 1

Note 1.—If formula for minimum elongation gives values of less than 25% for firebox steel, minimum allowable elongation shall be taken as 25%. If the material is over $^3/_4$ in. thick, a deduction from specific elongation of 0.125% is made for each $^1/_{32}$ in. specified above $^3/_4$ in., to a minimum of 20%. For material $^1/_4$ in. or less thick, elongation shall be measured on a gage length equal to (24 × thickness).

Bend Test.—The specimen to bend cold through 180° without cracking on outside of bent portion as follows: Material 1 in. or less thick, around a pin of diameter equal to thickness of specimen. Over 1 in., around a pin of diameter (2 × thickness of specimen).

Permissible variation in gage under that specified, not over 0.01 in. A homogeneity test is required for firebox steel. *Process.*—Steel shall be made by open-hearth or electric furnace, or both.

Note 2.—Elongation is measured on gage length of (24 × thickness of specimen), with reduction of 2.5% for each $^1/_{16}$ in. under $^5/_{16}$ in. Specimen shall bend cold through 180° without cracking on outside of bent portion, around pin of diameter equal to thickness of specimen.

Note 3.—*Process.*—Either open-hearth or electric furnace, or both. Forgings are annealed above critical temperature.

[a] Basic steel; acid steel, P = 0.05. [b] Basic steel; acid steel, P = 0.04. [c] Basic steel; acid steel, P = 0.06. [d] Maximum. [e] Elongation in 2 in. [f] Minimum. [g] Basic steel; acid steel, P = 0.07

Bend Test.—Specimen shall bend cold through 180° without cracking on outside of bent portion, around 1-in. pin for Class 1, and around 1 1/2-in. pin for Class 2.

Note 4.—*Process.*—Open hearth or electric furnace, or both.

Bend Test.—Specimen shall bend cold through 180° flat on itself without cracking on outside of bent portion. Quench bend test also required. (See p. 6-18). Shank of rivet shall bend cold through 180° flat on itself without cracking on outside of bent portion. Rivet head shall flatten while hot to diameter of (2 1/2 × diameter of shank) without cracking at edges.

Permissible Variation in Diameter.—±0.007 in. for bars up to 1/2 in. inclusive; ±0.01 in. for over 1/2 in. to 1 in., inclusive; ±0.012 in. for over 1 in. to 1 1/4 in., inclusive; ±0.015 in. for over 1 1/4 to 1 1/2 in., inclusive; ±0.022 in. for over 1 1/2 to 2 in., inclusive.

Note 5.—Open-hearth or electric furnace, or both. Permissible variation in gage not more than 0.005 in. under nor 0.01 in. above specified size. Bars shall be truly round to within 0.01 in. Same tests required as for rivet steel.

Note 6.—Open-hearth or electric furnace, or both. Minimum elongation in 2 in., 26%. For material over 3/4 in. thick, deduct 0.125% for each increase of 1/32 in. specified above 3/4 in.

Bend Test.—Specimen shall bend cold through 180° without cracking on outside of bent portion as follows: material of diameter or thickness 1 in. or less, flat on itself; material over 1 in. to 1 1/2 in. inclusive, around a pin of diameter equal to thickness of test specimen; material over 1 1/2 in. around a pin of diameter equal to (2 × thickness of test specimen).

Permissible Variation in Diameter.—±0.007 in. for diameters up to 1/2 in. inclusive; ±0.010 in. for over 1/2 to 1 in. inclusive; ±0.012 in. for over 1 in. to 1 1/4 in. inclusive; ±0.015 in. for over 1 1/4 to 1 1/2 in. inclusive; ±0.022 in. for over 1 1/2 to 2 in. inclusive; +3/64 to −1/64 in. for over 2 to 2 1/2 in. inclusive; +3/64 to −1/32 in. for over 2 1/2 to 3 in. inclusive.

Note 7.—Open-hearth, electric furnace, converter, or crucible. Class A castings need not be annealed unless so specified, or unless carbon content exceeds 0.3%. Class B castings shall be properly annealed, treatment depending on design and chemical composition of castings.

Note 8.—Silicon not under 0.2%. Electric furnace, open-hearth or other process approved by purchaser. All castings shall be heat treated, either annealed or normalized and never quenched. Cold bend test required when specified. Hydrostatic test required. The specification contemplates temperature up to 750° F.

Note **9.**—Air furnace, open-hearth or electric furnace. Castings with any section less than 1/2 in. thick are light castings. If no section is less than 2 in. thick, castings are heavy castings. Medium castings are those not included in foregoing classifications. Transverse tests, made on *arbitration bar* placed horizontally on supports 18 in. apart and tested under a centrally applied load, shall show following minimum breaking loads: Light castings, 1500 lb.; medium, 1750 lb.; heavy, 2000 lb. Deflection at center never less than 0.2 in. The arbitration bar is 1.20 in. diam., 23 in. long, cast in a thoroughly dry and cold sand mold, or in a core. The standard tensile test piece is 0.8 in. diam., 1 in. long between shoulders, with a fillet 7/8 in. radius, and ends to fit the holders of the testing machine.

Note 10.—Air furnace, open-hearth, or electric furnace. Castings must be sufficiently annealed.

Note 11.—Rolled from a bloom, slab pile, or box pile, made from reworked wrought or knobbled charcoal iron, free from iron scrap or steel.

Bend Test.—Specimen to bend cold through 180° flat on itself without fracture on outside of bent portion. Specimen when nicked 25% around for round bars or along one side for flat bars, with a tool having a 60° cutting edge, to a depth between 8 and 16% of diameter or thickness of specimen and broken by pressure or blows, shall show a wholly fibrous structure.

Maximum Variation in Gage.—0.01 in. for 1/4 in. nominal diameter, increasing by 0.001 for each 1/16 in. up to 5/8 in., and for each 1/8 in. from 5/8 in. to 1 7/8 in. diameter where tolerance is 0.026 in. Etch test required to show material to have been rolled from a bloom, slab pile or box pile, uniform and free from steel.

Note 12.—See Note 11; material must be twice worked, that is twice piled. Specimen to bend cold through 180° flat on itself in both directions without fracture on outside of bent portion. See Note 11 for nick bend test and etch test required. Bars must be truly round within 0.01 in and shall not be less than 0.005 in. over nor more than 0.02 in. over specified size.

Note 13.—Made from wrought iron free from iron scrap or steel.

Bend Test.—Specimen to bend cold through 180° around pin of diameter equal to diameter or thickness of specimen, without fracture on outside of bent portion. Specimen when heated between 1700 and 1800° F. to bend through 180° flat on itself without fracture on outside of bent portion. See Note 11 for nick bend test and maximum variation in gage. Etch test, structure to be uniform and free from steel.

Note 14.—Lap-welded tubes shall be made either by open-hearth or electric furnace, or both, or the knobbled, hammered charcoal iron process. Seamless tubes shall be made by either the open-hearth or electric furnace or both. Grade C tubes are seamless.

Flange Test.—For tubes not over 6 in. diameter, of thickness less than 10% of O.D., and not exceeding No. 6 B.W.G., a test specimen not less than 4 in. long shall have a flange turned over at right angles to the body of tube without cracking or showing any flaw. Flange to have a width of 1/8 to 1/2 in. measured from outside of tube. Width between these limits to be as follows:

O.D. of tube, in	Charcoal Iron	Open Hearth or Electric Furnace: Grades A and B	Open Hearth or Electric Furnace: Grade C
Up to 2 1/2 in., inclusive	12.5% of O.D.	15% of O.D.	75% of that required for Grades A and B
Over 2 1/2 in. to 3 3/4 in., inclusive	3/8 in.	3/8 in.	
Over 3 3/4 in. to 6 in., inclusive	10% of O.D.	10% of O.D.	

Flange test not required for other tubes.

Flattening Test.—For tubes except Grade C, of wall thickness not over 10% of O.D. and not exceeding No. 6 B.W.G., a section 2 1/2 in. long shall stand flattening between parallel plates until distance between plates is (3 × wall thickness) for seamless tubes, or (5 × wall thickness) for lap-welded tubes, without cracking or showing any flaw. For tubes except Grade C other than above, a 2 1/2 in. long section shall stand flattening until distance between parallel plates is (4 × wall thickness) for seamless and (6 × wall thickness) for lap-welded tubes. Lap-welded, charcoal iron tubes thicker than No. 6 B.W.G. shall be tested with weld 45° from point of maximum bend. Other charcoal iron, and all steel, lap-welded tubes, shall be tested with weld at point of maximum bend. A section 2 1/2 in. long of Grade C tubes shall stand flattening between parallel plates without cracking or showing any flaw until distance between plates is 1/2 O.D. but never less than (7 × wall thickness).

Hydrostatic Test.—Tubes under 5 in. diam. must stand an internal hydrostatic pressure of 1000 lb. per sq. in. and tubes 5 in. diam. and over, 800 lb. per sq. in., providing fiber stress corresponding to these pressures does not exceed 16,000 lb. per sq. in. for Grades A and B, and 18,000 lb. per sq. in. for Grade C. If fiber stress exceeds above values, test pressure P shall be determined by $P = (32{,}000\ t/D)$ for Grades A and B, and $P = (36{,}000\ t/D)$ for Grade C. t = tube thickness, in.; D = outside diameter, in. Lap-welded tubes shall be struck with a 2-lb. steel hammer near both ends while under test pressure. Permissible variations in wall thickness is zero under, and 2 B.W.G. over, for cold-drawn tubes or 3 B.W.G. over for hot finished tubes.

Note 15.—S = 0.25%. Open-hearth or electric furnace, or both. Specification covers plates 2 in. thick and under. Plates over 1 in. thick shall be heat treated.

Tensile Test.—Plates over 3/4 in. have elongation deduction of 0.125%, for each increase of 1/32 in., to minimum of 18% for flange, and 19% for firebox quality.

Bend Test.—Specimen shall bend cold through 180° without cracking on outside of bent portion when bent around a pin. Where t = thickness of specimen, diameter of pin to be:

	Up to 1 in. thick	1 1/2 in. thick	1 1/2 to 2 in. thick
Grade A, pin diameter	$1.5t$	$2t$	$2t$
Grade B, pin diameter	$2t$	$2t$	$2.5t$

Homogeneity test required for firebox steel only. Maximum variation in thickness = 0.01 in. under specified.

Note 16.—Si = 0.25% maximum. Open-hearth or electric furnace, or both. Specifications cover plates over 2 in. to 4 in. inclusive. Heat treatment required.

Tensile Test.—Plates over 2 1/2 in. thick have elongation deduction of 0.5% for each increase of 1/2 in., to minimum of 22% for Grade A, and 20% for Grade B.

Bend Test.—Specimen shall bend cold through 180° without cracking on outside of bent portion when bent around a pin of diameter (2 × thickness) for Grade A, and (2 1/2 × thickness) for Grade B specimens up to 3 in. inclusive, and (2 1/2 × thickness) for Grade A, and (3 × thickness) for Grade B specimens over 3 in. to 4 in. inclusive. Homogeneity test required.

3. WORKING PRESSURES

MAXIMUM ALLOWABLE WORKING PRESSURE (A.S.M.E. Code).—Maximum allowable working pressure on the shell of a boiler or drum, for temperatures not to exceed 700° F., is determined by the strength of the weakest course, computed as follows:

where P = maximum allowable working pressure, lb. per sq. in.; T = ultimate tensile strength stamped on shell plates by manufacturer, lb. per sq. in.; t = minimum thickness of shell plates in weakest course, in.; e = efficiency of longitudinal joint or ligaments between tube holes (whichever is least); R = inside radius of weakest course of shell or drum, in., if thickness of shell is less than 10% of radius, or R = outside radius if thickness is greater than 10% of radius; F = factor of safety or ratio of ultimate strength to allowed stress. For new constructions, F = 5. For temperatures exceeding 700° F., allowable stresses replacing $T \div F$ in formula [1] are given in Table 2.

Table 2.—Working Stresses of Plain Carbon Steels at Various Temperatures

Maximum Temperature, deg. F.	Minimum of specified range of tensile strength of material, lb. per sq. in.				
	45,000	50,000	55,000	60,000	75,000
	Allowable Working Stress, lb. per sq. in.				
700	9,000	10,000	11,000	12,000	15,000
750	8,220	9,110	10,000	11,200	13,000
800	6,550	7,330	8,000	9,000	10,200
850	5,440	6,050	6,750	7,400	8,300
900	4,330	4,830	5,500	5,600	6,000
950	3,200	3,600	4,000	4,000	4,000

Table 3, from Boiler Book of Hartford Steam Boiler Inspection and Insurance Co., gives the allowable pressures on boiler shells with joints of efficiencies as shown on page 6–26.

PRESSURES ALLOWED ON OLD BOILERS. (Suggested Rules Covering Existing Installations. Appendix to A.S.M.E. Code, 1933 Edition.)—Maximum allowable working pressure on shell of a boiler or drum shall be determined by formula [1], with factors of safety as given below. Boilers in service one year after these rules become effective shall be operated with a factor of safety of at least 4. Five years after these rules become effective, factor of safety shall be at least 4.5. In no case shall maximum allowable working pressure on old boilers be increased, unless they are being operated at a lesser pressure than would be allowable for new boilers, in which case the changed pressure shall not exceed that allowable for new boilers of the same construction.

The age limit of a horizontal-return tubular boiler having a longitudinal lap joint and carrying over 50 lb. per sq. in. pressure shall be 20 years, except that no lap-joint boiler shall be discontinued from service solely on account of age until 5 years after these rules become effective.

Second-hand boilers, *i.e.*, boilers where both ownership and location are changed, shall have a factor of safety of at least 5 1/2 one year after these rules become effective, unless constructed in accordance with the rules contained in the Power Boiler Section, when factor shall be at least 5.

Maximum allowable working pressure on a water-tube boiler, tubes of which are secured to cast-iron or malleable-iron headers, or which have cast-iron mud drums, shall not exceed 160 lb. per sq. in.

Maximum allowable working pressure shall not exceed 15 lb. per sq. in. on a boiler used exclusively for low-pressure steam heating.

The shell or drum of a boiler in which a typical "lap seam crack" is discovered along a longitudinal riveted joint for either butt seam or lap joint shall be permanently discontinued for use under steam pressure. By "lap seam crack" is meant the typical crack frequently found in lap seams extending parallel to the longitudinal joint and located either between or adjacent to rivet holes.

DRUM DESIGN.—The maximum diameter of boiler drums that can be built economically, particularly for bent-tube boilers with inherently low ligament efficiencies, limits increases in steam pressure. The use of steel of 70,000 lb. per sq. in. tensile strength for fusion welding, as permitted by the 1933 A.S.M.E. Code, allows pressure to be increased with a given drum. The code specification covers plate up to 4 in. thick, but no limit is placed on the thickness that may be fusion welded.

Two-plate construction is the most economical for fusion welded drums for bent-tube boilers. A thick plate is used for the tube sheet, with low ligament efficiency, and a

Diameter of Shell, Inches

thin plate, with high ligament efficiency is used for the wrapper. Ligament efficiency for bent-tube boilers with 3 1/2-in. tubes, of average spacing of 6 in. along the drum, is approximately 0.453; for sectional header cross-drum boilers it ranges from 0.65 to 0.75 or more, depending on the spacing of circulators. Fig. 1 gives limits of steam pressure for fusion-welded drums of 4-in. plate of 70,000 lb. tensile strength. Actual inside and outside diameters, corresponding to standard head dimensions are:

Nominal diam., in.	36	42	48	54	60	72
Actual inside diam., in.	32 5/8	38 5/8	44 3/8	50 7/8	57	69
Actual outside diam., in.	40 5/8	46 5/8	52 3/8	58 7/8	65	77

Forged drums will be of uniform thickness around the circumference, and with forged heads will weigh more than the thick-and-thin plate welded drums with welded heads, but may be made of steel of 75,000 per sq. in. tensile strength. Fig. 2 shows limiting steam pressures for forged seamless drums of 5-in. plate, 75,000-lb. tensile strength, of the following dimensions:

Nominal diam., in.	36	42	48	54	60	72
Actual inside diam., in.	31	37	43	49	55	67
Actual outside diam., in.	41	47	53	59	65	77

Fig. 3 gives longitudinal tube spacing necessary for the ligament efficiencies shown in Figs. 1 and 2.

Temperature stress on the inner surface of drums is approximately (110 × temperature

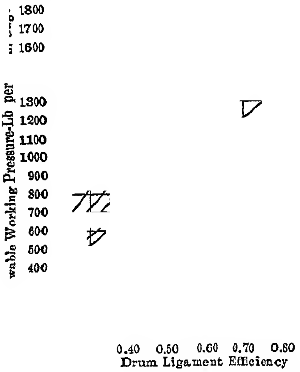

Fig. 1. Maximum Allowable Working Pressures of Fusion Welded Drums with Thick and Thin Plates

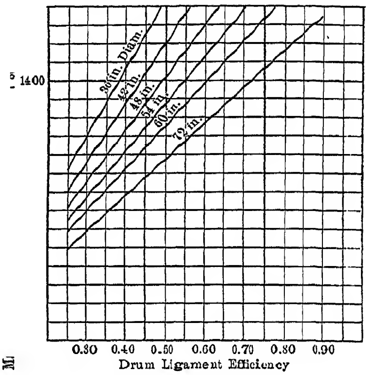

Fig. 2. Maximum Allowable Working Pressures of Forged Steel Drums

drop). Maximum allowable temperature drop T_m through the drum shell, therefore, is $T_m = (S_t - S_a)/110$, where S_t and S_a = respectively, actual and allowable stresses in the drum. Thus, in a drum of 70,000 lb. per sq. in. tensile strength, the permissible additional stress in that portion not pierced with tube holes may be 7600 lb. per sq. in., corresponding to a temperature drop of 69° F. These conditions would require that rate of heat absorption of drums over 2 in. thick be kept below 10,000 B.t.u. per sq. ft. per hr. See Fig. 4.

THICKNESS OF PLATES (A.S.M.E. Code).—The thickness of plate for any given working pressure may be computed by

$$t = (P \times R \times F) \div (T \times e), \qquad [2]$$

where e = efficiency of joint. Minimum thickness of any boiler plate under pressure shall be 1/4 in. Minimum thickness of plates in stayed surface construction shall be 5/16 in.

Minimum thickness of shell plates and dome plates after flanging to be as follows:

Diameter of shell, in.	Up to 36	36–54	54–72	Over 72
Thickness, in.	1/4	5/16	3/8	1/2

Minimum thickness of butt straps for double-strap joints to be as follows, intermediate values being found by interpolation:

Plates, in.	1/4 to 11/32	3/8 to 13/32	7/16 to 15/32	1/2 to 9/16	5/8 to 3/4	7/8	1	1 1/8	1 1/4	1 1/2
Straps, in.	1/4	5/16	3/8	7/16	1/2	5/8	11/16	3/4	7/8	1

For plate thicknesses over $1\,^1/_2$ in., butt-straps shall be at least $^2/_3$ as thick as the plate. Minimum thickness of tube sheets for horizontal return tubular boilers to be as follows:

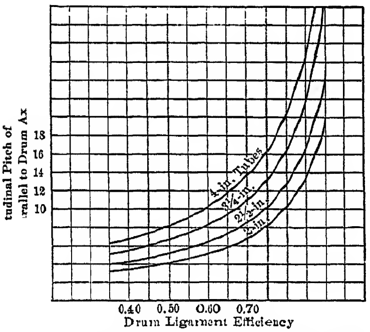
Diameter of tube sheet, in......	Up to 42	42–54	54–72	Over 72
Thickness, in...............	$^3/_8$	$^7/_{16}$	$^1/_2$	$^9/_{16}$

The resistance to crushing of steel plate is to be taken at 95,000 lb. per sq. in. of cross-sectional area.

HYDROSTATIC TESTS (A.S.M.E. Code).—Completed boilers to be subjected to hydrostatic test of $1\,^1/_2 \times$ maximum allowable pressure. Pressure to be so controlled that required test pressure will not be exceeded by more than 6%. Safety valves are to be removed, or each valve held to its seat by a clamp during test. Where it is impossible to calculate with a reasonable degree of accuracy the strength of a boiler structure, or any part thereof, a full size sample may be tested in accordance with a prescribed method. The maximum allowable working pressure of a structure by this method may be determined by

$$P = (HS/5E), \qquad [3]$$

where P = maximum allowable working pressure, lb. per sq. in.; H = hydrostatic pressure at proportional limit; S = average tensile strength of the material, lb. per sq. in.; E = average proportional limit of the material. S and E are determined from specimens cut from weakest sections, with axes parallel to direction of greatest stress. If specimens cannot be obtained, alternate method is to assume $E = 0.4\,S$ which gives $P = (H \div 2)$.



3. Longitudinal Pitch of Boiler Tubes for Various Ligament Efficiencies

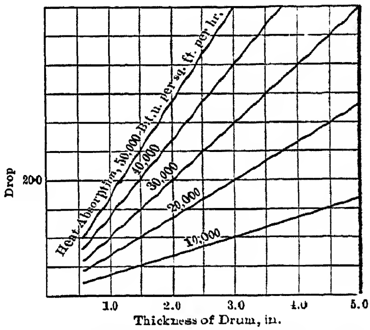


FIG. 4. Temperature Drop through Drums

4. BOILER JOINTS

LONGITUDINAL JOINTS (A.S.M.E. Code).—The distance between center lines of any two adjacent rows of rivets, or back pitch, measured at right angles to the joint should have the following minimum values: If P/D is 4 or less, minimum value is $2D$; if P/D is over 4, minimum value is $2D + 0.1\,(P - 4D)$, where P = pitch of rivets, in., in outer row where a rivet of inner row comes midway between two rivets in the outer row; or pitch of rivets in outer row less pitch of rivets in inner row, where two rivets in inner row come between two rivets in outer row (it is assumed that joints are of the usual construction, and rivets symmetrically spaced); D = diameter of rivet holes, in. On longitudinal joints, distance from centers of rivet holes to edges of plates, except rivet holes in the ends of butt straps, should be not less than $1.5D$ nor more than $1.75D$, measured from center of rivet hole to calking edge of plate before calking. Edge of plate is to be beveled to an angle not sharper than 70° to the plane of the plate, and as near thereto as practicable. Calking is to be done with a tool of such form that there is no danger of scoring or damaging the plate underneath the calking edge or of splitting the calking sheet.

Riveted longitudinal joints of a shell or drum exceeding 36 in. diameter shall be of butt and double-strap construction. This rule does not apply to that portion of boiler shell which is staybolted to the firebox sheet. Longitudinal joints of shell or drum less than 36 in. diam., may be lap-riveted, if the maximum allowable pressure does not exceed 100 lb. per sq. in. The longitudinal joints of horizontal return tubular boilers shall be

located above the fire line of the setting. In horizontal return tubular boilers with lap joints, no course shall be over 12 ft. long. In butt and double-strap construction, longitudinal joints of any length may be used. Butt straps and ends of shell plates forming longitudinal joints shall be rolled or formed by pressure, not blows, to proper curvature.

If shell plates in horizontal return tubular boilers are over $^5/_8$ in. thick, the portion of the plates forming the laps of circumferential seams exposed to fire or products of combustion shall be planed or milled as in Fig. 5, providing the requirements for strength of circumferential joints are complied with (see below).

CIRCUMFERENTIAL JOINTS.—The strength of circumferential joints in boilers whose heads are not stayed by tubes or through braces shall be at least 50% of that required for the longitudinal joints of the same structure. If tubes or stays relieve 50% or more of the load which would act on an unstayed solid head, the strength of the circumferential joints in the shell shall be at least 35% of that required for longitudinal joints. In the portion of the circumferential joints of horizontal return tubular boilers exposed to the products of combustion, shearing strength of rivets shall be at least 50% of the full strength of the plate corresponding to the thickness at the joint. Distance from center of rivet holes to edge of plate in boilers having headers supported by tubes or through stays, shall not be less than (1 $^1/_4$ × diam. of rivet hole). Back pitch between two rows of rivets shall not be less than (1 $^3/_4$ × diam. of rivet hole).

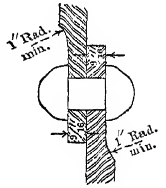

FIG. 5.

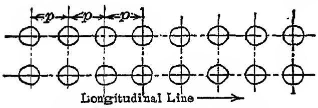
LIGAMENTS (A.S.M.E. Code).—When a shell or drum is drilled for tubes on a line parallel to its axis, the efficiency of the ligaments between tube holes is determined by formulas [4] and [5], where E = efficiency of ligament, P = unit length of ligament, in., p = pitch of holes, in., d = diameter of holes, in., n = number of holes in length P.

When pitch of tube holes on every row is equal (Fig. 6)

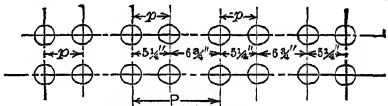
$$E = (p - d) \div p. \qquad [4]$$

When pitch of tube holes on any one row is unequal (Figs. 7 and 8)

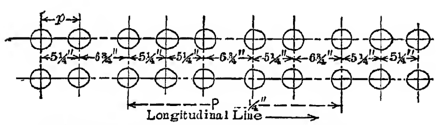
$$E = (P - nd) \div P. \qquad [5]$$



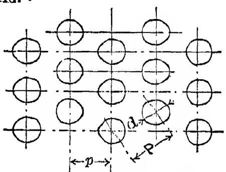
PITCH OF HOLES EQUAL IN EVERY ROW
FIG. 6



PITCH OF HOLES UNEQUAL IN EVERY SECOND ROW
FIG. 7



PITCH OF HOLES VARYING IN EVERY SECOND AND THIRD ROW
FIG. 8



Ligaments FIG. 9

Ligaments between tube holes which are subjected to a longitudinal stress are required to be at least 50% of the strength of ligaments which come between tube holes which are subjected to circumferential stress. If holes are so drilled as to form diagonal ligaments as in Fig. 9, their efficiency is given by the chart Fig. 10, in which abscissas are p/d and ordinates P/p, where p = longitudinal pitch of tube holes, in., P = diagonal pitch of tube holes, in., and d = diameter of tube holes, in. Compute values of p/d and P/p and read efficiency from the diagram. If the point so found falls above the curve of equal efficiency for diagonal and longitudinal ligaments, the longitudinal ligaments will be the weaker, and the efficiency then is computed from formula [4].

EFFICIENCY OF RIVETED JOINTS (A.S.M.E. Code).—Let X = efficiency = ratio of strength of unit length of riveted joint to the strength of the same length of a solid plate; T = tensile strength of material, lb. per sq. in.; t = thickness of plate, in.; b = thickness of butt strap, in.; P = pitch of rivets, in., on row having greatest pitch; d = diameter of rivet, after driving, in.; a = cross-section of rivet after driving, sq. in.; s = strength of rivet in single shear, lb. per sq. in.; S = strength of rivet in double shear, lb. per sq. in.;

c = crushing strength of mild steel, lb. per sq. in.; n = number of rivets in single shear in a unit length of joint; N = number of rivets in double shear in same length of joint.

Single-riveted Lap Joints:

A = strength of solid plate = PtT.
B = strength of plate between rivet holes = $(P - d)tT$.
C = shearing strength of one rivet in single shear = nsa.
D = crushing strength of plate in front of one rivet = dtc.
X = (B/A) or (C/A) or (D/A), whichever is least.

Double-riveted Lap Joints:

A and B as above, C and D to be taken for two rivets.
X = B, C, or D (whichever is least) divided by A.

Butt- and Double-strap Joint, Double-riveted:

A = strength of solid plate = PtT.
B = strength of plate between rivet holes in outer row = $(P - d)tT$.
C = shearing strength of two rivets in double shear, plus shearing strength of one rivet in single shear = $NSa + nsa$.
D = strength of plate between rivet holes in second row, plus shearing strength of one rivet in single shear in outer row = $(P - 2d)tT + nsa$.
E = strength of plate between rivet holes in second row, plus crushing strength of butt-strap in front of one rivet in outer row = $(P - 2d)tT + dbc$.
F = crushing strength of plate in front of two rivets, plus crushing strength of butt-strap in front of one rivet = $Ndtc + ndbc$.
G = crushing strength of plate in front of two rivets, plus shearing strength of one rivet in single shear = $Ndtc + nsa$.
H = strength of butt straps between rivet holes in inner row = $(P - 2d)2bT$.
Note.—This method of failure is not possible for thickness of butt straps required by A.S.M.E. Code, and the computation need be made only for old boilers in which thin butt straps have been used.
X = B, C, D, E, F, G, or H (whichever is least) divided by A.

Butt- and Double-strap Joint, Triple-riveted:

The same as for double-riveted, except that four rivets instead of two are taken for N in computing C, F, and G.

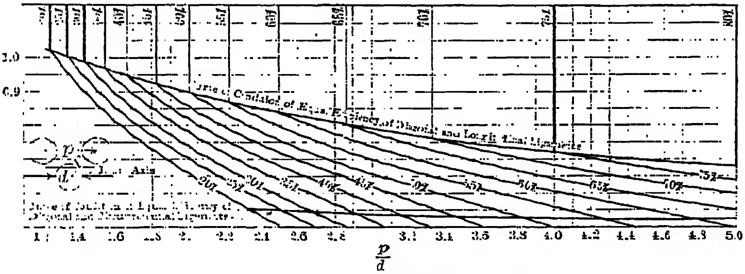


FIG. 10. Efficiency of Diagonal Ligaments

Butt- and Double-strap Joint, Quadruple-riveted:

A, B, and D the same as for double-riveted joints.
C = shearing strength of eight rivets in double shear and three rivets in single shear $= NSa + nsa$.
E = strength of plate between rivet holes in third row (the outer row being the first) plus shearing strength in single shear of two rivets in second row and one rivet in single shear in outer row = $(P - 4d)tT + nsa$.
F = strength of plate between rivet holes in second row, plus crushing strength of butt-strap in front of one rivet in outer row = $(P - 2d)tT + dbc$.
G = strength of plate between rivet holes in third row, plus crushing strength of butt-strap in front of two rivets in second row and one rivet in outer row $= (P - 4d)tT + ndbc$.
H = crushing strength of plate in front of eight rivets, plus crushing strength of butt-strap in front of three rivets = $Ndtc + ndbc$.
I = crushing strength of plate in front of eight rivets, plus shearing strength in single shear of two rivets in second row and one in outer row = $Ndtc + nsa$.
X = B, C, D, E, F, G, H, or I (whichever is least) divided by A.

RIVETING (A.S.M.E. Code).—Rivet and staybolt holes, and holes in braces and lugs to be drilled full size, or punched not to exceed $1/4$ in. less than full diameter for material over $5/16$ in. thick, and $1/8$ in. less for material not over $5/16$ in. thick, and then drilled or reamed to full diameter. Plates, butt straps, braces, heads and lugs to be bolted in position for drilling or reaming all rivet holes in boiler plates. Burrs and chips to be removed before riveting. Rivets shall be of sufficient length to completely fill rivet holes, and to form a head at least equal in strength to the bodies of the rivets. Rivets are to be machine-driven wherever possible, with sufficient pressure to fill rivet holes, and allowed to cool and shrink under pressure.

In computing ultimate strength of rivets in shear, the following values in lb. per sq. in, of cross-sectional area of the rivet shank are to be used: Iron rivets, single shear, 38,000; double shear, 76,000. Steel rivets, single shear, 44,000; double shear, 88,000.

WELDED JOINTS (A.S.M.E. Code).—The ultimate strength of a joint properly welded by the forging process shall be taken as 35,000 lb. per sq. in. when steel is manufactured according to specifications for steel plates of flange and firebox qualities for forge welding. Fusion welding may be used for butt- or lap-welded joints between door-hole flanges of furnace and exterior sheets, provided sheets are stayed around door-hole, and distance between flange and stays does not exceed staybolt pitch. Fusion welding may be used in lieu of riveted joints in fireboxes of internally-fired boilers, provided welds are between two rows of staybolts, or in case of flat surfaces, the welds are not less than one-half staybolt pitch from corner. Furnaces subjected to compression stresses may be fusion welded, provided welds are stress relieved. Ends of inner butt-straps of longitudinal joints may be fusion welded to edges of heads or circumferential butt-straps, provided carbon content of steel does not exceed 0.30%.

FUSION WELDING (A.S.M.E. Code).—Drums or shells of power boilers may be fabricated by means of fusion welding, a process of welding metals in the molten, or molten and vaporous state, without application of mechanical pressure or blows. Joint efficiency shall be taken as 90%. Tension tests are required for both joint specimen and the weld metal specimen. Tensile strength of both specimens must at least equal that of the minimum of range of the plate which is welded. Weld metal specimen must have minimum elongation of 20% in 2 in. Weld metal specimen tensile tests are not required for plate of thickness less than $5/8$ in. Bend-test specimen shall bend cold, until least elongation within or across entire weld on outside fibers is 30%. Specimens of weld metal shall have minimum specific gravity of 7.8. All longitudinal and circumferential welds shall be examined throughout their entire length by radiography.

Where plates of unequal thickness abut, the edge of the thicker shall be reduced to approximately the same thickness as the other. Welded drums shall be designed so that bending stresses are not brought directly on the welded joint. Corner welds shall be avoided, unless plates forming corners are independently supported.

Longitudinal and circumferential joints shall be of double-welded butt type, reinforced at center of weld on each side of plate by $1/16$ in. for plates up to $5/8$ in. incl., and $1/8$ in. for thicker plates. The reinforcement may be removed, but if not removed shall be reasonably free from irregularities, grooves, or depressions. Unreinforced holes shall not be located in a welded joint. Distance between edge of hole and edge of weld to be 1 in. for plates less than 1 in. thick; to be the thickness of the plates for plates 1 in. to 2 in. thick; and to be 2 in. minimum for plates over 2 in. thick.

All fusion-welded boiler drums and all connections attached by fusion welding shall be stress relieved, by uniform heating to 1100° to 1200° F. for a period of 1 hr. per 1 in. thickness, and allowed to cool slowly in still atmosphere.

All fusion-welded boiler drums shall be given a hammer test while under hydrostatic pressure of ($1\ 1/2 \times$ maximum allowable working pressure). Hammer test consists of a swinging blow with a hammer at 6 in. intervals on both sides of welded joint; weight of the hammer in pounds to approximately equal thickness of shell in tenths of an inch, but not over 10 lb. Following this, hydrostatic pressure of twice maximum allowable working pressure is maintained until inspections of all joints and connections are made.

5. BRACED AND STAYED SURFACES

FLAT SURFACES (A.S.M.E. Code).—Maximum allowable pressure for braced and stayed flat plates and surfaces which require staying is found by

$$P = C \times (T^2/p^2), \quad . \quad . \quad . \qquad [6]$$

where P = maximum allowable pressure, lb. per sq. in.; T = thickness of plate *sixteenths* of an inch; p = maximum pitch, in., measured between straight lines through the centers of the staybolts in the different rows, which lines may be horizontal, vertical or inclined; C = a constant whose values are as follows: Stays screwed through plates, with ends

riveted over, plates not over $^7/_{16}$ in. thick, 112; plates over $^7/_{16}$ in. thick, 120; stays screwed through plates, and fitted with single nuts outside of plate, or inside and outside nuts, omitting washers, 135; stays with heads not less than ($1.3 \times$ diam. of stay), screwed through plates or made a taper fit, having the heads formed on stays before installation and not riveted over, and having a true bearing on plate, 150; stays fitted with inside nuts and outside nuts and washers, diameter of washers being not less than $0.4\,p$ and thickness not less than T, 175.

If a doubling plate, of thickness t_1, covers the full stayed area of a flat boiler plate of thickness t, and at least $^3/_8$ in. thick, and is securely riveted thereto, t_1 being not less than $^2/_3\,t$, T in the formula may be taken as $^3/_4\,(t_1 + t)$, but not more than $1.5\,t$, and the value of C may be made $1.15\,C$. If two sheets are connected by stays, only one of which requires staying, the value of C is governed by the thickness of the latter.

To determine distance between centers of rivets or between edge of tube holes and centers of rivets attaching crowfeet of braces to braced surfaces, formula [6] is modified to

$$p = \sqrt{CT^2/P}, \qquad [7]$$

using $C = 135$. For other types of stays, use the value of C given for thickness of plate and type of stay used. To determine the maximum spacing between inner surface of shell and centers of rivets parallel to shell attaching crowfeet of braces to the head, use the above formula, with $C = 175$; for other types of stays take $C = 1.3$ times the value of C applying to thickness of plate and type of stay specified.

Table 4 gives maximum allowable pitch of screwed staybolts, with ends riveted over as computed by the foregoing formula. Values not given in Table 5 may be computed from the formula and used, provided pitch does not exceed $8\,^1/_2$ in. For staybolts adjacent to riveted edges bounding a stayed surface, distance from edge of staybolt hole to a straight line tangent to edges of rivet holes may be substituted for p. When edge of a flat stayed plate is flanged and riveted, distance from center of outermost stays to inside of supporting flange shall not exceed pitch of the stays, p, plus inside radius of flange. Maximum pitch p may be increased by staybolt hole diameter if staybolts are adjacent to a furnace door or other boiler fitting, tube hole, handhole, or other opening.

In water-leg boilers, staybolts may be spaced at greater distances than given in Table 4, if the portion of the sheet between staybolts has sufficient transverse strength to give a factor of safety of 5 at the maximum allowable pressure.

CURVED SURFACES (A.S.M.E. Code).—Two methods are given for finding maximum allowable pressure, the minimum value to be used:

a. Find pressure without making allowance for holding power of stays, but making allowance for weakening effect of stay-holes, or riveted longitudinal joint or other construction. To this add pressure found by formula [6] taking $C = 70$.

b. Find pressure without making allowance for holding power of stays, but making allowance for weakening effect of stay-holes or riveted longitudinal joint or other construction. To this pressure, add pressure corresponding to the strength of the stay for stresses given in Table 5, each stay being assumed to resist steam pressure on the full area of the external surface supported by the stay.

The determination of the maximum allowable working pressure for a wrapper sheet of a locomotive type boiler requires the use of a third rule, which is given in the Code.

SEGMENTS OF HEADS (A.S.M.E. Code) are to be stayed by head-to-head, through, diagonal, crowfoot or gusset stays, except that horizontal tubular boilers not over 36 in.

Table 4.—Maximum Allowable Pitch, in Inches, of Screwed Staybolts, Ends Riveted Over

Pressure, lb. per sq. in.	Thickness of Plate, in.

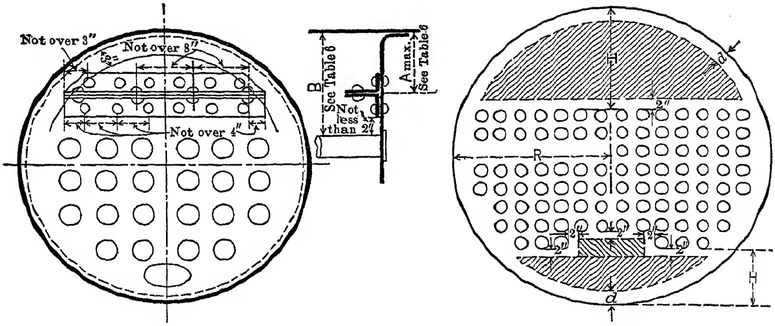

FIG. 11. FIG. 12.

Method of Staying Heads

diam. and designed for maximum pressures not over 100 lb. per sq. in., may have the segments of heads above the tubes stayed by steel angles as shown in Table 6 and Fig. 11. The areas to be stayed are indicated by the shading in Fig. 12.

$$\text{Net stayed area, sq. in.} \quad \frac{- d - 2)^2}{3} \quad \sqrt{} (H - d - 2) \; - 0.608,$$

the meaning of H and R being given in Fig. 12. The value of d may be found by

$$d = 5T/\sqrt{P}, \qquad [9]$$

where T = thickness of head in *sixteenths* of an inch, and P = maximum allowable pressure, lb. per sq. in.; or it may be taken as the outer radius of the flange of the head, not exceeding (8 × thickness of head), the larger value being used. Table 7 gives values for d, based on distance supported by flange of head; Table 8 gives net area to be stayed in shells where d = 3 in. Both tables are condensed from the Boiler Book of the Hartford Steam Boiler Inspection and Insurance Co.

If a horizontal return tubular boiler has a manhole opening below the tubes, flanged as specified under Dished Heads, p. 6–35, area to be stayed as indicated in the lower half of Fig. 12 may be reduced 100 sq. in. The surface around the manhole must be supported by through stays with nuts inside and outside at front head, and by attachments which distribute the stress at the rear head. The clear distance between bodies of braces, or of the inside braces where more than two are used, must not be less than 10 in. at any point.

In water-tube boilers with tubes connected to drum heads of diameter D, the area whose diameter is $(D - 2d)$ is to be stayed, d being found by formula [9]. No stays are required if the drum is 30 in. or less diameter, and the tube plate is stiffened by flanged ribs or gussets, providing a hydrostatic test to destruction of a similar unit shows a factor of safety of 5.

Stays are to be used in tube sheets of fire-tube boilers if distance between edge of tube holes exceeds maximum pitch of staybolts as given in Table 4.

STAYS AND STAYBOLTS (A.S.M.E. Code).—Specifications for holes for staybolts are given under Riveting. See p. 6–30.

Ends of staybolts or stays screwed through plates shall extend beyond the plate not less than two threads and must be riveted over or upset without excessive scoring of the sheets. Ends of staybolts 8 in. long or less must be drilled at least $^3/_{16}$ in. diameter,

Table 5.—Maximum Allowable Stresses for Stays and Staybolts

Description of Stays	Length between Supports	
	Not Over 120 Diameters	Over 120 Diameters
	Stress, lb. per sq. in.	
a. Unwelded or flexible stays less than 20 diameters long, screwed through plates and ends riveted over	7,500	......
b. Hollow steel stays less than 20 diameters long, screwed through plates and ends riveted over	8,000	......
c. Unwelded stays and unwelded portions of welded stays, except as specified in line *a* and line *b*	9,500	8,500
d. Steel through stays exceeding 1 1/2 in. diameter	10,400	9,000
e. Welded portions of stays	6,000	6,000

to a depth of at least 1/2 in. beyond the inside of plates, or hollow staybolts may be used. Flexible staybolts, or solid staybolts over 8 in. long need not be drilled. Staybolts in water-legs of water-tube boilers shall be hollow, or when solid must be drilled.

Riveted-over stay rods must be supported at intervals of at least 6 ft., length being measured from inside faces of stayed surfaces. Maximum allowable stress at area of least net cross-section of stays and staybolts is given in Table 5.

The least cross-sectional area of a stay must be taken in calculating the allowable stress; the strength at the weld also must be calculated with welded stays. Diameter of a screw stay is to be taken at bottom of the thread, or wherever diameter is least.

Stresses in Diagonal and Gusset Stays.—Area required for a diagonal stay is given by $A = aL/l$, where A = sectional area, sq. in., of diagonal stay; a = sectional area sq. in. of a direct stay to support the same surface; L = length of diagonal stay, in.; l = distance, in., at right angles to head, from surface supported to center of palm of diagonal stay. For staying segments in tube sheets, as in horizontal return tubular boilers, where $L < 1.15 \times l$ for any brace, diagonal stays may be calculated as direct stays, allowing 90% of the stress in Table 5.

Gusset Stays of triangular, right-angled plate, secured to angle bars along the sides at right angles, must have a cross-sectional area in the largest plane at right angles to the longest side of the plate, of not less than 10% more than required for a diagonal stay to support the same surface, assuming the diagonal stay to be at the same angle as the longest side of the gusset.

Braces and Brace Connections.—Braces shall be so designed that total load carried shall not exceed the unit stresses for unwelded stays given in Table 5. If welded, braces shall have a cross-sectional area at the weld as great as that computed for a stress of 6000 lb. per sq. in. Area of pins to resist double shear to be at least 75% of the required cross-sectional area of brace. Cross-sectional areas through blades of diagonal braces, where attached to shell, must at least equal the required rivet section, *i.e.*, 1.25 × required cross-sectional area of brace. Each branch of a crowfoot to be designed to carry 2/3 of total load on brace. Net sectional areas through sides of crowfoot or similar fastenings at rivet holes must be at least equal to the required rivet section.

Crown Bar and Girder Stays must be proportioned according to formula

$$\text{Maximum allowable pressure} = Cd^2t \div (W - P)DW, \quad . \quad . \quad . \quad . \quad [10]$$

where W = extreme distance between supports, in.; P = pitch of supporting bolts, in.; D = distance center to center of girders, in.; d and t = depth and thickness of girder, respectively, in.; C = constant, depending on number of supporting bolts as follows:

No. of supporting bolts.	1	2 or 3	4 or 5	6 or 7	8 or more
	7000	10,000	11,000	11,500	12,000

Stay Tubes supporting tube plates in multi-tubular boilers must have a sectional area as follows:

Total section of stay tubes, sq. in. $= (A - a)P \div T$ . . . . [11]

where A = area of that portion of plate containing the tubes, sq. in.; a = aggregate area of holes in tube plate, sq. in.; P = maximum allowable pressure, lb. per sq. in.; T = working tensile stress allowed in tubes, not to exceed 7000 lb. per sq. in. Pitch to be determined by formula [6] using values for C given in Table 9. If ends of tubes are not shielded from radiant heat, reduce C by 20%. Tubes are to project about $1/4$ in. and be slightly flared at each end. Stay tubes, when threaded, to be not less than $3/16$ in. thick at bottom of thread; nuts on stay tubes are not advised. For a nest of tubes, take $C = 140$ and p = mean pitch of stay tubes. For spaces between nests of tubes, p = horizontal distance center to center of bounding rows of tubes and C as in Table 9.

Table 9.—Values of C for Determining Pitch of Stay Tubes.

Pitch of Stay Tubes in Bounding Rows	No Nuts Outside of Plates	With Nuts Outside of Plates
Where there are two plain tubes between two stay tubes.......	$C = 120$	$C = 130$
Where there is one plain tube between two stay tubes..........	$C = 140$	$C = 150$
Where every tube in the bounding rows is a stay tube and each alternate tube has a nut..................................	....	$C = 170$

6. DISHED HEADS AND STEAM DOMES

DISHED HEADS (A.S.M.E. Code). **Convex Heads.**—For a blank unstayed convex head which is a segment of a sphere, with pressure on the concave side,

$$t = (8.33\ PL/2T), \quad \text{[12]}$$

where t = thickness of plate, in.; P = maximum allowable pressure lb. per sq. in.; L = inside radius to which head is dished, in.; T = tensile strength, lb. per sq. in. When two radii are used, the longer shall be used as the value of L. If the radius is less than 80% of the diameter D of the shell to which the head is attached, t shall be at least that found by making $L = 0.8D$. L shall never exceed D.

Concave Heads.—When pressure is on the convex side, maximum allowable pressure shall not be over 60% of that for convex heads of the same dimensions with pressure on the concave side.

Manhole Openings.—For dished heads with manhole openings, t must be increased 15% or at least $1/8$ in. over that called for by the formula, unless it has a flanged opening supported by a flue. Manhole openings are to be flanged to a depth of at least $3t$, measured from the outside, for plate up to 1 $1/2$ in. thick, and 3 in. plus thickness of plate for plates exceeding 1 $1/2$ in. thick. Dished heads thinner than those called for by formula [12] must be stayed as flat surfaces with no allowance for holding power due to the spherical form. The corner radius of an unstayed dished head, measured on the concave side, must be not less than $3t$ and never less than $0.03\ L$.

STEAM DOMES, if used, should be constructed in accordance with the Code.

Inside Diameter 24 in. or Over.—Riveted longitudinal joints to be butt- and double-strap construction, or dome may be made seamless of one piece of steel pressed into shape. Its flange shall be double-riveted to the shell.

Inside Diameter Under 24 in.—If (inside diameter, in. × maximum allowable working pressure) does not exceed 4000, flange may be single-riveted to shell and may be lap-type if computed with factor of safety of not less than 8.

The longitudinal joint of a dome may be butt welded, and the dome flange may be double full-fillet lap welded to the shell, in place of riveting, without requiring X-ray examination. Flanges shall be formed with an inside corner radius of at least $2\ t$ for plates 1 in. thick or less, and at least $3\ t$ for plates over 1 in. thick; t = thickness of plate.

7. BOILER TUBES

PRESSURES ALLOWED (A.S.M.E. Code).—Maximum allowable working pressure for seamless steel tubes for pressures below 875 lb. per sq. in., and lap welded wrought-iron tubes below 358 lb. per sq. in. may be found by

$$P = [\{(t - 0.039)/D\} \times 18{,}000] - 250, \quad \text{[13]}$$

and for lap-welded steel tubes for pressures of 875 lb. per sq. in. and above by

$$P = \{(t - 0.039)/D\} \times 14{,}000, \quad \text{[14]}$$

and for lap-welded wrought-iron tubes for pressures of 358 lb. per sq. in. and above, by

$$P = \{(t - 0.039)/D\} \times 10{,}600, \qquad [15]$$

where P = maximum allowable pressure, lb. per sq. in.; t = thickness of tube wall, in.; D = outside diameter of tube, in. See Table 10. Maximum working pressures for superheater tubes are the same as for boiler tubes.

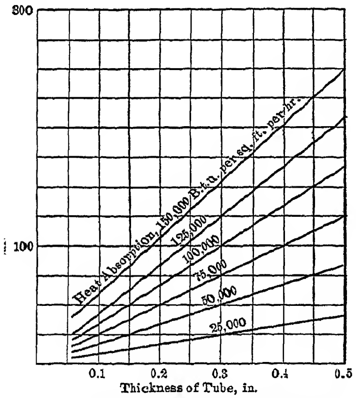
The minimum thickness of tubes for fire-tube boilers, for maximum allowable pressures not over 175 lb. per sq. in. is as follows:

Diam., in.	From.............	1	2 1/2	3 1/4	4	5
	To less than.......	2 1/2	3 1/4	4	5	6
Thickness, B. W. G.............		13	12	11	10	9

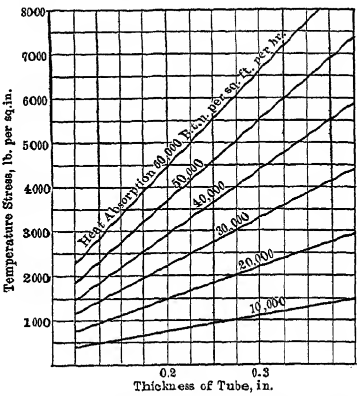
For each increase of one gage in thickness over the above, the maximum allowable pressure will be increased by (200 lb. ÷ tube diam. in.). For cross-sectional area of stay-tubes, see Stays and Staybolts, p. 6–30.

For copper tubes for water-tube boilers formula [16] has been recommended for maximum working pressure, notation being as before. Copper tubes should not be used for pressures over 250 lb. or temperatures over 406° F. See Table 11.

$$P = [\{t - 0.039)/D\}12{,}000] - 250 \qquad [16]$$



13. Temperature Drop through Carbon Steel Tube Walls



. 14. Temperature Stress in Carbon Steel Superheater Tubes

Temperature Stresses.—Figs. 13 and 14 from a paper by Perry Cassidy (Joint meeting Engrs. Soc. Western Penna. and Pittsburgh Section, A.S.M.E., Oct. 15, 1935) give data from which temperature stress in tubes may be determined. For higher rates of heat absorption, as in tubes exposed to furnace radiation, multiply temperature drop given in Fig. 13 by 1.10.

The temperature difference between boiling water and inside scale-free tube surfaces generally is small. Film conductance or transfer rates will be from 2000 to 3000 B.t.u. per hr. per sq. ft. per deg. F. So long as the inside tube surface is in contact with boiling water, temperature drop generally does not exceed 50 deg. F. in the first row of boiler tubes for high radiating temperatures, and 25 to 30 deg. for moderate furnace temperatures. The temperature of the outside surface of front-row scale-free boiler tubes, may be obtained by adding from 15 to 50 deg. to temperature corresponding to drum pressure and then adding temperature drop through tube wall.

For 1400 lb. per sq. in. drum pressure, maximum temperatures of outer surfaces of front-row boiler tubes may be as follows, based on 588° F. water temperature;

Heat absorption, B.t.u. per sq. ft. inside surface per hr.	50,000	75,000	100,000	125,000	150,000
Max. temperature, 3 1/4-in. tubes, 0.375 in. thick....	683	715	748	780	813
Max. temperature, 4-in. tube, 0.45 in. thick.........	694	732	770	808	846

Fig. 15 shows why wall and boiler tubes exposed to furnace radiation must be absolutely free from scale in high-pressure high-capacity boilers. Dense hard sulphate scale will have a thermal conductivity of from 12 to 15 B.t.u. per sq. ft. per hr. per deg. F. per in. thickness. Soft, less dense scale, such as carbonate may have lower conductivity, and it is possible for thin deposits of scale to have conductivity of 2 to 6.

Boiler tubes shielded from furnace radiation, with corresponding low rates of heat absorption may not be damaged by overheating due to reasonable scale deposits, although there are other objections to scale deposits besides overheating. Scale in any part of the boiler may imply scale in the front bank tubes and wall tubes.

TUBE HOLES AND ENDS (A.S.M.E. Code).—Tube holes to be drilled full size from solid plate, or punched at least 1/2 in. smaller in diameter than full size and then drilled, reamed or finished with a rotating cutter to full size. Sharp edges of holes on both sides of plate are to be removed.

Fire-tube boilers are to have both ends of tubes rolled and beaded, or rolled and welded at firebox or combustion chamber end. Ends of all tubes, suspension tubes, and nipples must be flared not less than 1/8 in. over the diameter of tube hole on all water-tube boilers and superheaters, or flared not less than 1/8 in., rolled and beaded, or flared, rolled and welded. Projection through tube sheets or headers to be not less than 1/4 in., nor more than 1/2 in. before flaring.

SIZE OF BOILER TUBES.—Table 12 gives dimensions of boiler tubes sanctioned by the A.S.M.E. Code for stationary fire-tube power boilers, together with their calculated surface per foot of length, and the length per square foot of surface, both external and internal, for allowable pressures up to 175 lb. per sq. in.

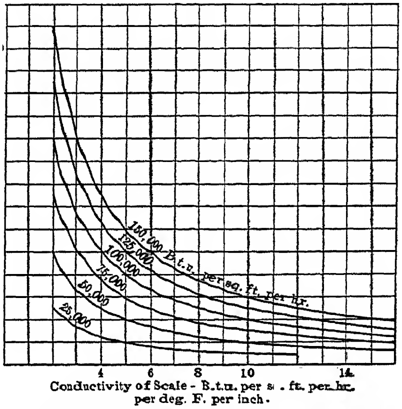


Fig. 15. Temperature Drop through Boiler Scale 0.01 in. Thick

HOLDING POWER OF EXPANDED TUBES.—The safe holding power of expanded tubes with smooth tube seats often is a factor in boiler design. The holding power of such seats varies, depending on the type of finish. Fig. 16 gives the safe holding power of drilled and reamed tube seats properly expanded and flared. It will be noted that up to a tube thickness of 0.2 in., holding power of the 2-in. tube seat 1 in. wide is greater than allowable stress in the tube. The 3 1/4-in. and 4-in. tube seats are stronger than the tubes below a thickness of 0.12 in. Holding power of the seat is based on an approximate factor

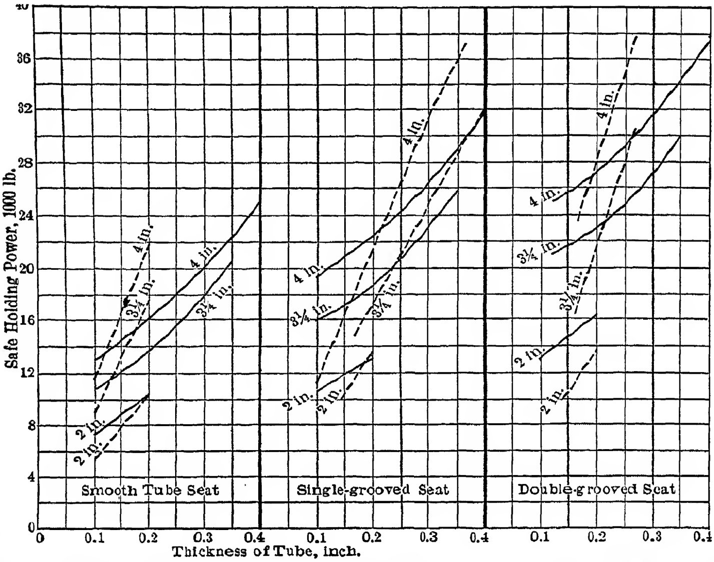

Fig. 16. Holding Power of Expanded Tubes. Tube seat 1 in. wide. Temperatures below 750° F.

of safety of 2, governed by initial slip of the tube resulting in leakage. The ultimate factor of safety is correspondingly higher. Fig. 16 shows also holding power of tube seats with single and double grooves. A change in the width of these tube seats will only affect holding power of the smooth portion.

Eccentric loading on tube seats, due to beam action or other causes, may result in high moments at the tube seat which require careful analysis to determine the safety.

8. BOILER FITTINGS

FLANGES AND FLANGED FITTINGS should conform to the standards of the American Standards Association. Dimensions of flanges of all valves and pipe fittings of cast iron or steel are given in Section 5. See pp. 5-42 to 5-68.

CAST-IRON AND MALLEABLE HEADERS FOR WATER-TUBE BOILERS.—Maximum pressure allowed 160 lb. per sq. in. for cast iron; 350 lb. per sq. in. for malleable. Cast-iron headers tested to destruction must stand hydrostatic pressure of at least 1200 lb. per sq. in.; malleable, 2250 lb. per sq. in. Hydrostatic test required on all new headers

Table 12.—Dimensions of Standard Boiler Tubes for Fire-tube Boilers

with tubes attached, as follows: Cast iron, 500 lb. per sq. in.; malleable, ($2\,^1/_2 \times$ working pressure), but never less than 500 lb. per sq. in.

MANHOLES. WASH-OUT HOLES (A.S.M.E. Code).—Minimum size of elliptical manholes 11×15 in. or 10×16 in. Minimum diameter, circular manholes, 15 in. Handholes, whose greatest dimension exceeds 6 in. to be reinforced as manholes. Reinforced rings to be of rolled, forged or cast steel, and of minimum thickness according to Table 13. Manhole frames on shells or drums shall have proper curvature, and

Table 13.—Minimum Thickness of Independent Riveted Reinforcing Rings or Flanges

Thickness of shell plate, in..			1/4–11/32	3/8–13/32	7/16–15				1 1/8–2	over 2
Thickness of reinforcing ring or flange, in.	1/8	3/16	1/4	5/16	3/8	7/16	1/2	5/8	3/4	

on boilers over 48 in. diam. shall be riveted to shell with two rows of rivets. Their strength, and also that of rivets in shear, must at least equal tensile strength of a cross-sectional area determined by product $t \times (d - 2)$, where t = shell thickness (using 90% efficiency), and d = diameter of opening in shell in the finished construction. Manhole plates are to be of rolled, forged or cast steel. Minimum width of bearing surface for gasket, $^{11}/_{16}$ in. Maximum thickness of gasket, $^1/_4$ in. when compressed.

A manhole must be located in front head below the tubes of horizontal return tubular boilers of 48 in. or more diameter. Smaller boilers to have either manhole or handhole below tubes. A manhole is required in the upper part of shell or head of fire-tube boilers over 40 in. diameter, except vertical fire-tube boilers or internally-fired boilers not over 48 in. diameter. Smaller boilers must have handholes or manholes above the tubes.

Wash-out plugs or handholes are to be provided as follows: In traction, portable or locomotive-type stationary boilers: Rear head below tubes, 1; front head at crown sheet, 1; lower part of water leg, 4; near throat sheet, 1. In vertical fire-tube boilers, except those of steam fire engines or boilers 24 in. diam. or less: shell at line of crown sheet, 3; shell at water line or opposite fusible plug when used, 1; shell at lower part of water leg, 3. In vertical fire-tube boilers, submerged tube type; shell, in line with upper tube sheet, 2 or more. All boilers 24 in. diam. or less shall have at least one opening for inspection, and two openings in addition to blow-off for washing out boiler. Openings shall not be less than 1 in. pipe size and shall be fitted with brass plugs.

THREADED OPENINGS.—Minimum number of threads for all pipe connections of 1 in. diam. or over is given in Table 14. Threaded joints shall not be used, either at the shell or at terminating end of connections over 3 in. pipe size, where maximum allowable working pressure exceeds 100 lb. per sq. in.

Table 14.—Minimum Number of Threads for Pipe Connections

Size of connection, in.	1 & 1 1/4	1 1/2 & 2	2 1/2 to 4	4 1/2 to 6	7 & 8	9 & 10	12
Threads per in.	11 1/2	11 1/2	8	8	8	8	8
Min. number threads required.	4	5	7	8	10	12	13
Min. thickness of material, in.	0.348	0.435	7/8	1	1 1/4	1 1/2	1 5/8

FUSIBLE PLUGS (A.S.M.E. Code).—Fusible plugs, if used, shall be filled with tin with a melting point between 400 and 500° F. and shall be renewed once each year. Least diameter of fusible metal shall be not less than $^1/_2$ in., except for maximum allowable working pressures of over 175 lb. per sq. in. or when it is necessary to place a fusible plug in a tube, in which case least diameter of fusible metal shall be not less than $^3/_8$ in., the tube wall being not less than 0.22 in. thick or sufficient to give four threads. Fusible plugs, if used, shall be located at lowest permissible water level of the boiler. Fusible plugs are not advisable when boilers are to operate at working pressures over 225 lb. per sq. in.

9. SAFETY VALVES

Safety valves are designed to open automatically to relieve excess pressure in boiler or pressure vessel to which they are attached. They may be of the direct, spring-loaded pop type. Dead weight or weighted-lever safety valves shall not be used.

DISCHARGE CAPACITY (A.S.M.E. Code).—The capacity of all safety valves of $^1/_2$ in. size or larger shall be the manufacturer's guarantee, and shall be plainly marked by him in such a way as not to be obliterated in service. Markings shall give: *a*, name of manufacturer; *b*, size, in.; *c*, pressure, lb.; *d*, blow-down, lb.; *e*, capacity, lb. per hour; *f*, A.S.M.E. Standard. Capacity is to be figured at a pressure 3% higher than setting pressure, and with valve adjusted for blow-down given under *d*.

SAFETY VALVE REQUIREMENTS (A.S.M.E. Code).—Each boiler shall have at least one safety valve. If water heating surface exceeds 500 sq. ft., or steam generating capacity exceeds 2000 lb. per hour, two or more safety valves are required. Safety valve

capacity for each boiler shall be such that the safety valve or valves will discharge all the steam that can be generated by the boiler without allowing pressure to rise more than 6% above maximum allowable working pressure, or more than 6% above highest pressure to which any valve is set, if this pressure is less than maximum allowable working pressure.

One or more safety valves on every boiler shall be set at or below maximum allowable working pressure. The remaining valves may be set within a range of 3% above such pressure, but the range of setting of all of the valves on a boiler shall not exceed 10% of the highest pressure to which any valve is set.

Safety valves shall be of such a type that no failure of any part can obstruct free and full discharge of steam from the valve. They may be of the direct spring-loaded pop type, with seat and bearing surface of the disc inclined at an angle between 45° and 90° to the center line of the spindle. The valve shall be rated at a pressure 3% in excess of that at which it is set to blow, and a blow-down of not more than 4% of said pressure, but never less than 2 lb. Safety valves may be used which give any opening up to full discharge capacity of area of opening at inlet of the valve. Weighted-lever safety valves are prohibited.

Safety valves shall operate without chattering and shall be set and adjusted as follows: To close after blowing down not more than 4% of the set pressure, but not less than 2 lb. in any case. For spring-loaded pop safety valves, operating at pressures up to and including 300 lb. per sq. in., blow-down shall not be less than 2% of set pressure. Blow-down as marked on valve shall not be reduced.

Seats and discs must be of corrosion-resistant metal, the seat being so fastened to the body that there is no possibility of its lifting.

Springs shall not show a permanent set exceeding 1/16 in., 10 minutes after being released from a cold compression test which closes the springs solid. The valve must be able to lift from its seat at least 1/10 diameter of the seat before the coils of the springs are closed or before there is any other interference. No springs shall be used for any pressure greater than 10% above or below that for which it was designed.

Safety valves over 3 in. size and used for gage pressures greater than 15 lb. per sq. in., shall have flanged inlet connection.

Safety Valves on Superheaters.—Every attached superheater shall have one or more safety valves near the outlet, whose discharge capacities may be included in determining

Table 15.—Safety Valves for Fire-tube Boilers

number and size of safety valves for the boiler if there are no intervening valves between the superheater safety valve and the boiler, and if discharge capacity of safety valves on the boiler as distinct from the superheater, is at least 75% of the total valve capacity required. Every independently-fired superheater which may be shut off from the boiler, permitting superheater to become a fired pressure vessel, shall have one or more safety valves with a discharge capacity equal to 6 lb. of steam per sq. ft. of superheating surface, measured on side exposed to hot gases. The number of safety valves installed shall be such that the total capacity is at least equal to that required. A soot blower connection may be attached to the same outlet from the superheater as used for safety valve connection. Safety valves on superheaters discharging superheated steam at temperatures over 450° F. shall have a casing, including base, body, bonnet and spindle, of steel, steel alloy or equivalent heat-resisting material, a seat and a disc of nickel composition or equivalent, a flanged inlet connection, and a fully-exposed spring outside the casing, protected from escaping steam.

SAFETY VALVES FOR LOCOMOTIVES.—Requirements are same as those given for power boilers with following exceptions: Every locomotive boiler shall have at least two safety valves of capacity sufficient to prevent a rise of more than 5% above specified boiler pressure. Safety valves shall be set to pop at pressures not over 6 lb. above working steam pressure.

SAFETY VALVE CAPACITY REQUIRED (A.S.M.E. Boiler Code).—Minimum aggregate relieving capacity of the safety valve or valves required on a boiler is determined on the basis of 6 lb. of steam per hr. per sq. ft. of boiler heating-surface for water-tube boilers. For all other types of power boilers, minimum allowable relieving capacity is determined on the basis of 5 lb. of steam per hr. per sq. ft. of heating-surface, where maximum allowable working pressure is above 100 lb. per sq. in. For maximum allow-

able working pressures of 100 lb. per sq. in. or less, the basis is 3 lb. of steam per hr. per sq. ft. of boiler heating-surface. Tables 15 and 16, condensed from the Boiler Book of the Hartford Steam Boiler Inspection and Insurance Co., give the number and dimensions of valves required on various sizes of boilers at different pressures, the tables being computed in accordance with the foregoing rules, and average lifts for the valves being assumed as follows:

Diam. of valve, in.	1	1 1/4	1 1/2	2	2 1/2	3	3 1/2	4	4 1/2
Assumed lift, in.	0.04	0.04	0.05	0.06	0.06	0.08	0.09	0.10	0.11

In all cases valves shall conform to the requirement that they discharge all steam that can be generated by the boiler without allowing pressure to rise more than 6% above highest pressure to which any valve is set. If two or more safety valves are used on a boiler, they may be either separate or twin valves, made by mounting individual valves on Y-bases, duplex, triplex or multiplex valves having two or more valves in the same body casing. Safety valves shall be connected to the boiler independently of any other steam connection and attached as closely as possible to the boiler. They shall be connected, so as to stand in an upright position, with spindle vertical whenever possible. Each safety valve connection shall have a cross-sectional area not less than the combined inlet areas of all valves mounted thereon. In fire-tube boilers, openings in the boilers for safety valves shall not be less than given in Table 17. No valve of any description shall be placed between the safety valve or valves and boiler, nor on discharge pipe between the valves and atmosphere. Discharge pipes must be at least the full size of the valve and must be fitted with an open gravity drain at or near each safety valve where water of condensation may collect. Each valve must have an open gravity drain through the casing below the level of valve seat. If a muffler is used, it shall have sufficient outlet area to prevent back-pressure from interfering with proper operation and discharge capacity of valve. The discharge capacities given in Table 17 may be interpolated to determine the values for intermediate pressures.

SUPERHEATERS, ECONOMIZERS AND AIR HEATERS

1. SUPERHEATERS *

When heat is added to water in a closed vessel, and the water is transformed into steam, the temperature of the liquid and the steam is equal and substantially constant, so long as any water remains as liquid. The quantity of heat that can be added to a unit weight of water also is a constant, provided that pressure remains constant throughout the process. When all the water has been transformed into steam, further addition of heat raises the temperature and heat content of the steam, which then is *superheated*. If the steam be withdrawn from presence of the water as it is generated, and passed through heated tubes it will become superheated. This is the principle of the superheater used in commercial practice. The superheater is that portion of the steam generating

* The curves in this section and the notes accompanying them are from The Trend of Boiler Design, by Perry Cassidy, presented at a joint meeting of Engrs. Soc. of Western Penn. and Pittsburgh Section, A.S.M.E., Oct. 15, 1935.

unit which receives saturated steam from the boiler proper, and in which further transfer of heat occurs from the hot gases of combustion to the steam.

Superheaters are installed, almost invariably, in large and modern power plants throughout the world. The efficiency of a power-generating unit, including boiler and turbine, will be higher with a superheater than without one. Also, further economies are realized in the plant as a whole because of reduced steam consumption of prime movers and auxiliaries. On the other hand, superheaters would not be advisable in certain cases, for example, where process or heating steam is used and constant temperatures are desired.

INTEGRAL SUPERHEATERS.—Integral superheaters, convection or radiantly-heated, are placed within the boiler setting, and receive heat from the same source as the boiler proper. Choice of location of the superheater, relative to water-tube heating surface, depends on several factors. For small amounts of superheat, a conventional type convection superheater, in boilers of the Babcock & Wilcox type usually is located above the first and second boiler passes (overdeck superheater). See Fig. 1. If higher steam temperatures are required, the superheater may be placed between tube rows, where it is subjected to higher temperature gases (interdeck superheater). Although close to the furnace, the boiler surface retained between it and the furnace shields the superheater tubes from direct furnace radiation. See Fig. 2.

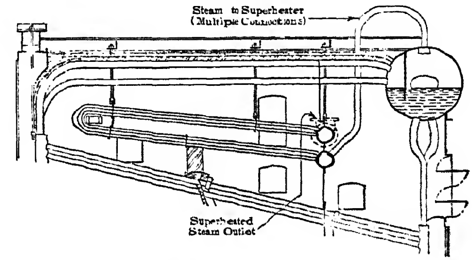

Fig. 1. Babcock & Wilcox Overdeck Superheater

Convection Superheater.—Early types of convection superheaters comprised a multiplicity of U-shaped tubes, connected in parallel between inlet and outlet headers. Saturated steam was supplied to one end of the inlet header through a single pipe connection from the boiler drum. Uniform distribution to individual tubes was insured by baffles in the header and ferrules in the tubes. Modern (1935) superheaters also have parallel circuits, but each tube is longer and is formed into an element comprising several return bends, giving a longer path between inlet and outlet connections. Several tube connections, spaced at intervals, from boiler steam drum to superheater inlet header, effect uniform distribution of saturated steam.

Inasmuch as superheater elements, in any conventional location in the setting, are exposed to relatively high temperature gases, tube metal may be overheated to the point of failure unless tubes are properly cooled by the flow of steam through them. Hence, uniform distribution of steam to all tubes is desirable, to maintain sufficient velocity of flow with a minimum pressure loss between drum and superheat outlet. Maximum steam temperature requirements are met either by radiant-heat superheaters combined with convection superheaters, or by separately fired superheaters.

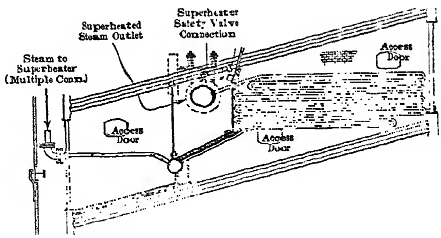

Fig. 2. Babcock & Wilcox Interdeck Superheater

In Stirling-type boilers, the convection superheater is between the first and second tube banks. The degree of superheat attained in normal operation is governed by extent of superheating surface, by effect of gas baffles in tube banks, and by amount of boiler surface preceding superheater. See Fig. 3.

Radiant Superheaters are exposed to the furnace, and the transfer of heat is by direct radiation. They usually are placed in one or more walls of the furnace, and in some cases replace a water wall. Operating conditions are more severe than with the convection type because of the high temperatures to which they are exposed. Greater attention must be given to design, to avoid tube failure due to overheating. This necessitates high steam flow, which is accomplished at the expense of pressure drop. In this type of super-

heater, steam temperature decreases with increased load. It, therefore, seldom is used except in combination with the convection superheater. Properly proportioned, such a combination can maintain constant steam temperature over a wide range of load.

COMBINATION OF CONVECTION AND RADIANT HEAT SUPERHEATERS.—In the convection type superheater, increase in superheat usually accompanies increase in load. This may be 20 to 30% higher at maximum load than when boiler is operated at lowest desired capacity. With radiant-heat superheaters, increase in load tends to decrease the amount of superheat. Within certain limits, the closer the superheater is to the furnace the more uniform will be superheat throughout the operating range. This is because the superheater becomes, in effect, a combination convection and radiant-heat superheater. A comparatively constant degree of superheat can be obtained by a properly arranged combination of convection and radiant-heat superheaters, connected in series. The steam flows first through the convection superheater. This combination is subject to limitations, as steam velocity must be high enough, especially in the radiant-heat superheater, to prevent overheating of metal, and under some conditions an excessive pressure drop through the two superheaters would result.

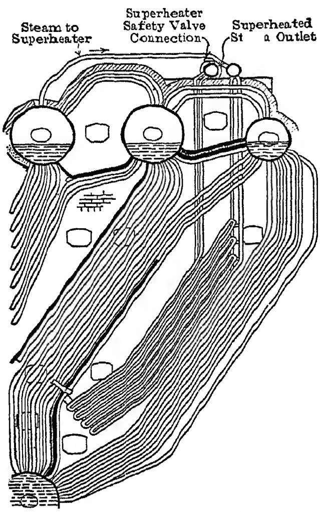

Fig. 3. Convection Superheater in Stirling Boiler

SEPARATELY FIRED SUPERHEATERS are advantageous where a high degree of superheat is required. Certain processes call for steam temperatures that would cause operating difficulties if attempted with an integral superheater. A change in prime movers or industrial process, may require a higher steam temperature from a plant already in operation. The most economical solution may be a separately fired superheater supplied from the main steam line. One superheater can serve several boilers.

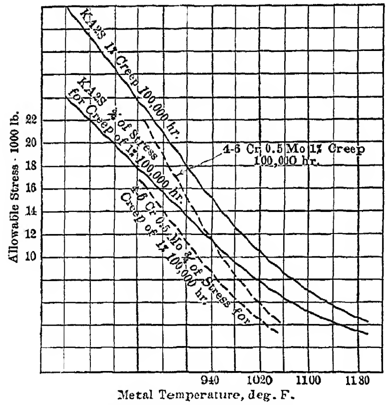

Fig. 4. Creep Stress in Alloy Superheater Tubes

Separately fired superheaters require carefully supervised operation. Interrupted steam flow, occasioned by decreased demand for steam, will lead to excessive superheat, unless firing conditions are carefully controlled.

Various arrangements of heating surface are used. Best economies result with a counterflow of steam and gas, the gases usually making three or four passes over the heating surface. Provision may be made against danger of excessive tube temperatures, or tube burning, by a combination of parallel flow in the high-temperature portion, and counterflow in the lower-temperature portion of the unit. Temperatures also may be controlled by rate of firing and variation in excess air supply.

A Babcock & Wilcox separately fired superheater using oil fuel, at the Delray Station of Detroit Edison Co., is designed to heat 90,000 lb. of steam per hr. from 700 to 1100° F., at 400 lb. per sq. in. pressure. Superheater consists of three sections in series. The upper section is a convection section of carbon steel tubes and has a counterflow of steam and gases. The intermediate section also is a convection section, with special alloy tubes and parallel flow of steam and gases. The lower section is a radiant-heat section. It consists of refractory-covered special alloy steel tubes, which form sidewalls and floor of the furnace.

REHEATER SUPERHEATERS may be placed in the main boiler setting or may be separately fired. ' They must offer low frictional resistance to flow of steam and provide uniform flow through all tubes. Counterflow of steam and gases make possible a higher degree of superheat with a given amount of heating surface. Required steam temperatures may be obtained by control of firing rates in separately fired types, by desuperheater equipment, by by-passing gases, or by using a live steam reheater in series with the main flue gas reheater, in integral type units.

TUBE STRESSES. USE OF ALLOY TUBES.—In determining thickness of superheater tubes, stresses due to temperature gradient through tube walls, and creep stress also must be considered. In superheater tubes, used at high temperatures, creep stress should govern. Ordinary carbon steel tubes should not be used at metal temperatures exceeding 900–950° F., depending on the pressure, as the actual working stresses in such tubes may exceed limiting creep stress.

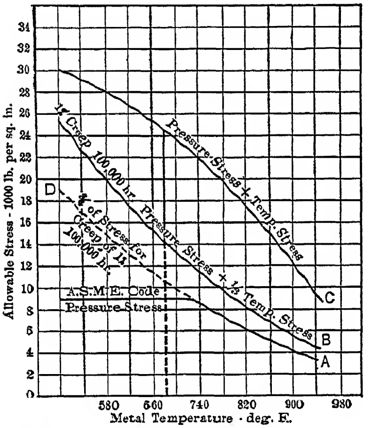

Fig. 5. Allowable Stresses in Seamless Steel Superheater Tubes. Low-carbon Tubes, A.S.M.E. Code, Grade A

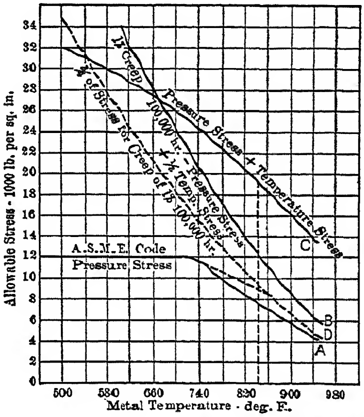

Fig. 6. Allowable Stresses in Seamless Steel Superheater Tubes. Medium-carbon Tubes, A.S.M.E. Code, Grade C

A number of superheaters now (1935) supply steam at temperatures of 850° F. and more. In these, special alloy steel tubes are used in the superheater where metal temperatures are highest. Satisfactory alloys for superheater tubes, where temperature on inside of tube exceeds 950° F. are:

Alloy	C	Mn	Si	Cr	Mo	
4–6 Cr, 0.5 Mo....	0.15	0.35	0.25	4.0–6.0	0.4–0.6	
KA2S...........	0.07 max.	0.60 max.	0.75 max.	16.5–20.0	....	7.0–10.5

The 4–6 Cr, 0.5 Mo tube is satisfactory for metal temperatures at the inside surface up to 1050° F, and the KA2S for temperatures up to 1150–1200° F. Thermal conductivity of KA2S alloy is about 0.4 that of carbon steel, and its thermal expansion is about 30% greater at 900° F. and 40% greater at 500° F. Temperature stress for a given rate of heat absorption and tube thickness is about 3.5 times that of carbon steel. Increase of creep stress permissible at 900° F. is in about the same ratio as that of carbon steel. KA2S tubes should not be expanded into carbon steel headers or drums, but should be resistance-welded to short lengths of carbon steel tubes, which then are expanded into tube seats. Thermal conductivity of 4–6 Cr, 0.5 Mo alloy is slightly less than that of carbon steel, and its thermal expansion is about 0.9 that of carbon steel at 900° F. and 0.94 at 500° F. Higher creep stresses are permissible than with carbon steel tubes, but the resistance to oxidation is no better. Fig. 4 gives creep stresses of KA2S and 4–6 Cr, 0.5 Mo tubes.

Figs. 5 and 6 give limiting stresses for superheater tubes of grade A low-carbon steel, specification S-17 of A.S.M.E. Boiler Code, and of grade C medium carbon steel, 60,000 lb. per sq. in. minimum tensile strength. The lower curves correspond to values allowed by the

Code (see Table 10, p. 6–37). Required thickness for pressure stress only may be calculated on the basis of stress values in the lower curves by the formula $t = Pd/2S$, where t = wall thickness, in., P = pressure, lb. per sq. in.; d = inside diam., in.; S = permissible stress at temperature of inner surface of tube (curves A, Figs. 5 and 6). (Pressure stress + $^1/_3$ temperature stress for elastic range) should not exceed stress corresponding to 1% creep in 100,000 hours (Curve B, Figs. 5 and 6); and (pressure stress + full temperature stress) should not exceed limit of curve corresponding to 0.9 yield point. In Figs. 5 and 6, curve C governs for temperatures to the left of the heavy vertical line, and curve B governs for temperatures to the right of it. In Fig. 6, the Code values (Table 10) are lower than curve D, and the dotted line joining curves A and D should be used in preference to curve A for temperatures of 750° to 950° F. In no case should thickness of tube be less than the values in Table 10. Fig. 7 shows required thickness of superheater tubes for various pressures and temperatures. It indicates that Code thickness (Table 10) should be increased for pressures of 720 lb. with temperature above 900° F., and for pressures of 400 lb. with temperature above 950° F.

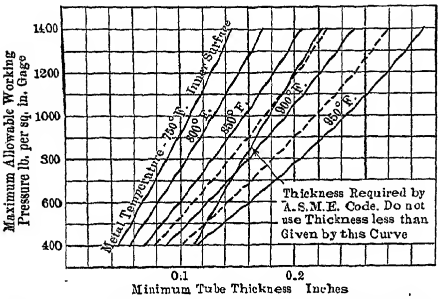

FIG. 7. Required Thickness for Superheater Tubes for Pressure Stress

EFFECT OF FEEDWATER TEMPERATURE.—For the same fuel burning rate, superheat increases with decrease in temperature of feedwater. Gas weights and temperatures entering superheater will not change, but steam weight through superheater will be less, since more heat is required to evaporate each pound of water. For the same capacity, degrees of superheat will vary, approximately, in direct proportion to B.t.u. absorbed per pound of steam in boiler and superheater (and economizer, if any), for a change of not more than 150° F. in feed temperature. Excessive superheat may result if it is necessary to cut out the feedwater heater and supply the boiler with cold feedwater.

SETTING OF SUPERHEATER SAFETY VALVES.—In all superheaters, a certain steam velocity through the tubes is necessary for protection against burning. Superheater safety valves, therefore, should be set to operate at a pressure below that of the boiler (saturated) safety valves, to insure that superheater valves blow first. Should safety valves on boiler and superheater be set for the same pressure, boiler safety valves would blow first, and the superheater would have little or no flow of steam, with consequent danger of tube burning.

REGULATION OF AMOUNT OF SUPERHEAT.—Higher steam temperatures demand some means of automatically regulating amount of superheat. Four methods are available: 1. Temperature of superheated steam is reduced to required temperature after it leaves superheater. This has been accomplished by: *a*, a controlled water spray in inlet or discharge pipe; *b*, placing tubes in the water space of steam and water drum, through which the part of the superheated steam passes, and after being cooled, is mixed with the rest of the superheated steam; *c*, by-passing part of the total superheated steam generated through cooling tubes, submerged in water from the steam and water drum. 2. Only part of the heated gases pass over the superheater; the quantity by-passed around it is regulated by dampers, or by using a divided furnace. 3. Interstage desuperheating, where two superheaters are placed in series; temperature of superheated steam entering second superheater is regulated to maintain a constant final temperature. 4. Some superheated steam is recirculated back to the steam and water drums through a desuperheating zone; velocity of the steam through the superheater thus is increased without increasing delivered steam; this method requires a compressor to recirculate the steam. Present (1935) practice is limited to desuperheating and to by-passing of the gases in conventional boiler designs. In the latter case, design should be such that the damper is not exposed to excessive temperature. In method 1 the spray pipe is simply a nozzle in a steam main or in a mingling chamber. Fig. 8 shows a submerged type desuperheater, which can be used either interstage or at superheater outlet. It is connected directly to the boiler and designed for natural circulation on the water side, steam generated being discharged behind the separator in the steam and water drum. A butterfly valve regulates the quantity of superheated steam passing through the submerged tubes.

AMOUNT OF HEATING SURFACE in superheaters varies widely for each installation. It depends on several variables, including temperature, pressure, load, location of superheating surface relative to boiler heating surface, amount of superheat required, temperature of gases, and heat transfer rate. High temperatures and pressures require more heating surface than do low temperatures and pressures, because of the greater ratio of heat in the superheat to the latent heat per pound of steam at high pressures. Quantity of steam and amount of superheat required are determined both by process and power requirements. Location of superheater may be selected arbitrarily in accordance with good engineering practice, and should not involve mechanical or operating difficulties (cleaning, excessive tube temperatures, etc.). Temperatures of gases will depend on such factors as type of fuel, combustion conditions, amount of water-tube surface or water screen swept by the gases before they strike superheater, etc. Conductance will vary as temperature and velocity of gases. The gases should be limited to a temperature that will not produce excessive superheater tube temperatures. This may be accomplished by the addition of water tube surface ahead of the superheater. Velocity of gases is limited by the allowable draft loss. The nearer the superheater is to the furnace, the more important is the effect of radiant heat as a factor in determining conductance.

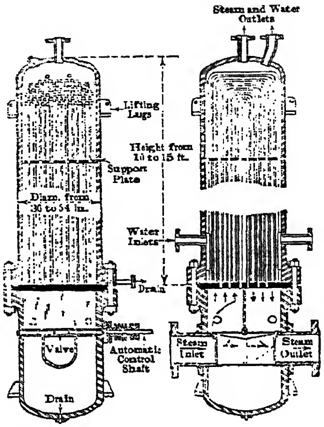

FIG. 8.

SUPERHEATER SURFACE REQUIRED.—The relation between heat absorbed by steam in the superheater and that given up by gases of combustion, radiation included, is

$$AUT = \quad - t_2); \; AUT = W_1 c_1(T_1$$

where A = area of superheater surface, sq. ft., U = conductance, B.t.u. per hr. per sq. ft. per deg. mean temperature difference; T = logarithmic mean temperature difference between steam and gases of combustion; W, W_1 = respectively, weight of gases of combustion and weight of steam passing through superheater per hr.; c, c_1 = respectively, mean specific heat of gases of combustion and of steam; t_1, t_2 = respectively, gas temperature entering and leaving superheater, deg. F.; T_1, T_2 = respectively, temperature of superheated steam and saturated steam.

Surface required is $A = H/UT$, where H = heat to be absorbed by superheater, B.t.u. per hr. = $(h_2 - h_1)$; h_1, h_2 = respectively, total heat of superheated and saturated steam, B.t.u. (see Steam Tables).

$$T = \frac{\text{(Maximum temperature difference)} - \text{(Minimum temperature difference)}}{\log_e \{\text{(Maximum temperature difference)}/\text{(Minimum temperature difference)}\}}$$

Conductance U varies with temperature of gases, gas velocity, steam velocity, tube size and spacing, surface cleanliness, and other variables of minor importance. Approximate values for 2-in. tube elements, varying with position of superheater are

Mass flow.................	2000	3000	4000
U, interdeck superheater....	7–7.5	8.5–9.5	10–11.5
U, overdeck superheater.....	6–6.5	7.5–8.5	9–10

Mass flow is defined as lb. of gas or steam per hr. per sq. ft. of minimum free flow area.

Temperature drop through the steam film in superheater tubes for various rates of heat absorption and steam mass flows is given in Fig. 9. Temperature drop $t_d = H/U_f$; $U_f = 0.95\,G/1000$, where U_f = steam film conductance, B.t.u. per hr. per sq. ft. inside tube surface; G = mass steam flow; other notation as above. The curves are based on a specific heat of steam of 0.55 and a friction factor of 0.004. For any other specific heat or friction factor, temperature drop will vary inversely as the square root. Fig. 10 shows the relation between mass flow, tube thickness and rate of steam generation for 2-in. tubes on 3-in. centers.

Table 1 gives superheater surface required for various degrees of superheat under the

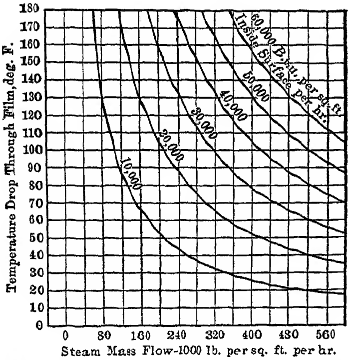

Fig. 9. Effect of Steam Mass Flow and Heat Absorption on Temperature Drop through Steam Film in Superheater Tubes

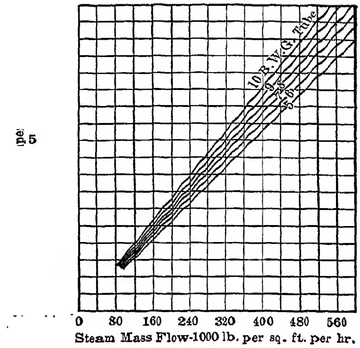

Fig. 10. Steam Mass Flow in 2-in. Superheater Tubes, Spaced 3-in. Centers

conditions specified, the superheater having 2-in. continuous tube elements on 3-in. centers. The assumed section is 94 tubes wide with elements approximately 11 ft. long.

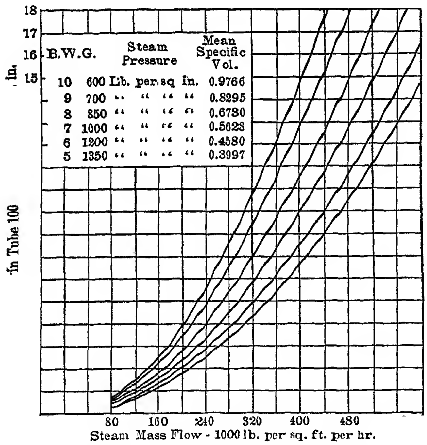

Fig. 11. Pressure Drop in 2-in. Straight Superheater Tubes. Steam Temperature 800° F.

In the overdeck position the superheater is parallel flow above the first pass of the boiler, and counterflow above the second pass, or *vice versa.* Hence, the average of the two logarithmic mean temperature differences is used. Surface required overdeck is much greater than interdeck for the same number of water tubes in the bank, due both to lower conductance, and to lower mean temperature difference, the latter having the greater significance. A unit with overdeck superheater may cost less than one with interdeck superheater, as the latter usually requires a double-deck boiler and increased head room. Also, it requires more time and care to bring a boiler on the line from cold with an interdeck than with an overdeck superheater for the same number of tubes in the boiler bank. The position of the interdeck superheater necessitates lower rates of heat input, so that the gas temperature in this location will not cause excessive superheater tube temperatures during the period of zero steam flow.

FUEL REQUIRED FOR SUPERHEATING.—When combined efficiency of boiler and superheater equals that of boiler alone, fuel required for superheating the same

Table 1.—Superheater Surface Required for Various Superheats

Conditions: Capacity, 300,000 lb. steam per hr.; pressure, 410 lb. per sq. in. at superheat outlet; gas weight, 350,000 lb. per hr.; gas mass flow, 4000 lb. per hr. per sq. ft. of minimum free flow area through superheater.

Interdeck. Entering Gas, 1950° F.			Overdeck. Entering Gas, 1300° F.	
Superheat, deg. F.	Sq. ft., Parallel Flow	Sq. ft., Counterflow	Superheat, deg. F.	Sq. ft.
100	1400	1396	100	3220
200	3032	2962	200	8200
300	5275	4940	....	....
400	8835	7550	....	....

weight of steam is in direct proportion to the additional B.t.u. absorbed per pound of steam. The increase in fuel required for various degrees of superheat at 410 lb. per sq. in. superheated steam pressure, and 200° F. initial feedwater temperature is

Superheat, deg. F.	25	50	75	100	150	200
Additional fuel, percent	1.82	3.56	5.17	6.70	9.54	12.37

The potential energy of each pound of steam is increased by the same percentage, and for a given amount of work the steam weight required is proportionately less. From the standpoint of heat units absorbed, which is the measure of capacity, no additional fuel is required for a given absorption whether superheated or saturated, provided combined efficiency of boiler and superheater is the same as for boiler alone, but steam weight is reduced, due to the greater heat absorption per pound of superheated steam.

PRESSURE DROP IN SUPERHEATER TUBES can be expressed by

$$p = (400\, fV/D) \times (G/100{,}000)^2$$

where p = pressure drop, lb. per sq. in., f = friction factor; V = specific volume of steam, cu. ft. per lb.; D = inside diam. of tube, in.; G = steam mass flow, lb. per hr. per sq. ft. of free flow area. Bends will increase p from 50 to 100%, depending on their number per 100 ft. of tube and their radius. Additional pressure drop for each 90-deg. bend, expressed in equivalent feet of straight pipe is, approximately,

Radius of bend, tube diameters	1	2	3
Equivalent straight pipe, ft.	6.2	4.3	3.3

Pressure drops of 20–25 lb. per sq. in. per 100 ft. of tube are not excessive. Fig. 11 shows pressures drops in 2-in. tubes of various thicknesses.

2. ECONOMIZERS

The primary function of an economizer is to utilize part of the heat in flue gas to heat feedwater. There is always a most economical temperature of flue gases, above and below which steam costs are greater. Excessive reductions in flue gas temperature so increase capital investment and fixed charges on the increased heating surface necessary as to offset any gain in efficiency, and corresponding fuel economy.

GENERAL TYPES OF ECONOMIZERS.—Economizers are either of wrought steel or cast iron. Present-day practice with wrought steel economizers, favors using an economizer with each boiler. The individual economizer operates when the boiler operates, has no by-pass flues, and air leakage is a minimum. Cast-iron economizers generally utilize flue gas from two or more boilers, and have by-pass flues.

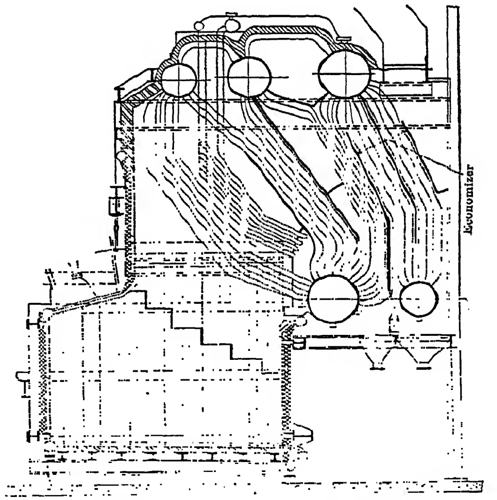

FIG. 12. Stirling Boiler Equipped with Integral Economizer

Economizers are either integral or independent. Integral economizers are located in the boiler setting, and connected directly to the boiler. See Fig. 12. Independent economizers usually are located above, or behind, the boiler. Connection to boiler drum may be through a single connection and valve, or directly through tubes, with no collecting header.

TREND OF ECONOMIZER DESIGN AND PRACTICE.—Early economizers were cast iron, including both tubes and headers. The tubes were set vertically in a flue between boiler and stack, and by-passes were common. Water and gas velocities were low, with corresponding low conductances. In smaller sizes, water flowed in parallel through all tubes. Larger sizes were in three or more sections, water flowing in parallel through tubes of each section, but in series through the sections. Later, steel tubes ex-

panded into headers ("boiler section type") tended toward large weight and space reduction. See Fig. 13.

Modern economizer practice dates from 1920, when means were developed for removing air and contained gases from water before it entered the economizer. Effective counterflow of gas and water, and long flow-paths for water are provided. Tubes usually are of smaller diameter than the boiler tubes. Gas velocities are high, and limited only by draft loss and power expense for draft fans. Water velocities, high enough to insure good heat transfer rates, and long flow paths have eliminated local convection circulation of water. Flow is forced one way, non-circulating, limited only by allowable excess pump power. Horizontal tubes, connected by a series of hair-pin bends, forged return bends, or combinations of both, eliminate stresses due to variation in length between hot tubes at the top and cooler tubes at the bottom. The upflow of water causes steam formed due to lack of water flow, especially in stand-by service, to rise to the top. Hot water will displace the steam, which tends to eliminate possibility of collapse of steam in pockets by condensation, with resultant water hammer. Wrought steel return bends with integral flanges, joining straight, and single- or multi-looped tubes, result in a flexible arrangement, without restraint on metal expansion, and obviate the possibility of cross connection between the several series flows of water. The latest (1935) horizontal wrought steel return bend economizer eliminates collecting headers by leading each series tube directly to the boiler drum. See Fig. 14.

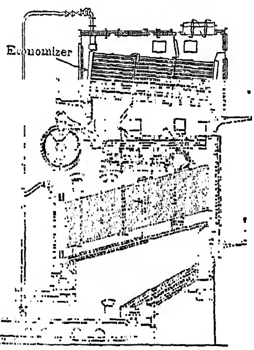

FIG. 13. Babcock & Wilcox Section Type Economizer

STEAMING ECONOMIZER.—A steel tube economizer designed to steam at higher rates of output, is known as a steaming economizer. In this economizer, each series tube is led directly to the boiler drum. Provision also is made to recirculate water when starting up. The steaming economizer is most useful in high capacity installations, where the boiler practically amounts to a water screen protecting the superheater, and boiler exit gas temperatures are high.

FACTORS AFFECTING EFFICIENCY.—The larger the economizer surface, the higher the gas velocity and temperature, and the lower the feedwater temperature, the greater will be the increase in efficiency effected by the addition of an economizer to a given boiler. Counterflow of gas and water gives greater heat absorption with less surface than does parallel flow.

With the exception of steaming economizers, economizer heating surface should be designed to limit maximum feedwater temperature, under any operating condition, to at least 40° F. below saturation temperature in the boiler. More surface than this probably would cause water in the economizer to reach the steaming point should boiler feed be cut off. Resumption of feed to the boiler would project water and steam from some forms of economizer into the boiler, partially emptying the economizer. On refilling economizer, temperature strains would set up, resulting in leakage, or water hammer might occur, causing serious trouble.

Economizer surface installed will vary with load conditions, feed temperature, fuel, extent to which gases are cooled, ratio of gas weight to water weight, etc. In non-steaming economizers, and where no air heaters are used, the surface usually is 40 to 60% of boiler heating surface. If air heaters are included, the surface usually approximates 25 to 30%. The surface of integral economizers ranges from 25 to 50% of boiler heating surface. The surface in steaming economizers ranges from 140 to 280% of boiler heating surface.

Temperature of gases entering economizer will vary with different types of boilers, operating loads, combustion conditions, etc. The temperature to which the gases can be cooled, in passing through the economizer will vary with amount of heat to be absorbed by feedwater, entering feed temperature, dew point of the gas (with low inlet feed temperture this is a limiting factor because of external corrosion), and economical exit temperature below which any gain in efficiency would be offset by increased cost.

For a definite amount of economizer surface and set temperature ranges, increase in gas velocity increases conductance. Gas velocity for a fixed amount and arrangement of surface is limited by allowable draft loss. With counterflow of gas and water, the mean temperature difference between gases and water is greater for economizer surface than for boiler surface beyond the superheater. Thus, less surface is necessary for a given degree of gas cooling, even if the conductance per degree difference is the same for both, and it is

practicable to design the economizer for higher conductance to further reduce the amount of economizer heating surface.

Gas velocities through cast-iron economizers usually are low, resulting in low conductance. Lack of facilities to properly keep cast-iron tubes externally clean also lowers conductance. In the typical cast-iron economizer, with a gas mass flow approximating 1500 lb per hr. per sq. ft. of gas passage area, a conductance of 2.5 to 3.5 B.t.u. per hr. per sq. ft. per deg. F. mean temperature difference may be expected. Increasing gas mass flow to 3000 lb. increases conductance to 5 to 6 B.t.u. Steel tube counterflow economizers utilize high gas velocities. At higher boiler steaming rates, conductance in a steel tube economizer will be from 12 to 13.5 B.t.u. per hr. per sq. ft. per deg. F. mean temperature difference for a gas mass flow of approximately 6500 lb. per hr. Draft loss through steel tube economizers under these conditions depends primarily on the gas mass flow and the height of the economizer. Feedwater temperatures will vary widely, depending on the source, *i.e.*, raw water, condenser hotwell, or feedwater heater.

DETERMINATION OF SURFACE REQUIRED.—The relation between heat absorbed by the water, and heat given up by the gases is:

$$AUT = Wc(t_1 - t_2);\ AUT = W_1 c_1(T_1 - T_2)$$

where A = area of economizer surface, sq. ft.; U= conductance, B.t.u. per hr. per sq. ft. per deg. mean temperature difference; T =logarithmic mean temperature difference between water and gases of combustion (see p. 6–47); W =weight of gases passing through economizer per hr; W_1=weight of water passing through economizer per hr.; t_1, t_2 = temperatures of entering and leaving gases, respectively, deg. F.; c and c_1 = mean specific heats of gas and water, respectively; T_1, T_2 = temperatures of leaving and entering water, respectively, deg. F. Surface required is either

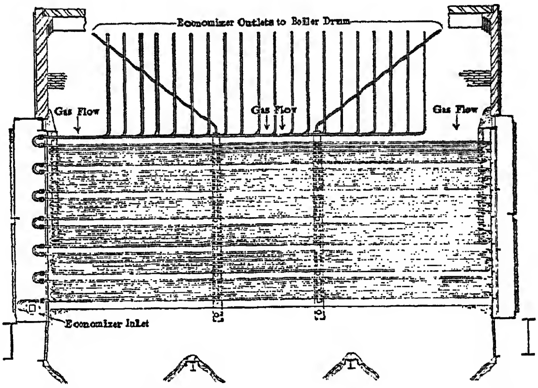

FIG. 14. Babcock & Wilcox Wrought Steel Continuous-tube Return Bend Economizer

$$A = H_w/UT \quad \text{or} \quad A$$

where H_w, H_g = heat absorbed by water or released by gas, respectively, B.t.u. per hr.; other notation as above.

Economizer surface required for various temperature drops in a 2-in. steel tube economizer is as follows, for conditions specified below. The advantage of counterflow over parallel flow is apparent.

Gas temperature drop, deg. F.	100	200	300	400	500
Sq. ft. surface, counterflow	1,143	2,592	4,440	7,020	10,920
Approximate rows high	5	12	20	31	48
Sq. ft. surface, parallel flow	1,145	2,621	4,630	7,820	15,350
Approximate rows high	5	12	21	35	68

Conditions: Capacity, 300,000 lb. water entering at 200° F.; gas mass flow, 6200 lb. per hr. per sq. ft. of minimum free flow area; entering temperature of gas, 900° F.; gas weight, 350,000 lb. per hr.; assumed economizer section 18 tubes wide, 24 ft. long; tube spacing, 3 1/2 in. centers.

Approximate draft loss for the 48 high counterflow economizer under above conditions is 3.25 in. of water. Increasing economizer section from 18 to 22 rows wide, increases required surface by 12.6% to 12,300 ft., but draft loss is reduced 35% to approximately 2.1 in. of water. Water pressure drop through economizer also is reduced about 35%. The increase in fixed charges and decrease in fan and pump power must be considered in order to determine which unit is more economical.

CORROSION AND CLEANING.—**External Corrosion** is due to condensation of the moisture content of the gases. Condensation begins when gases reach the dew point. Gases in contact with tubes reach the dew point sooner than gases in the main stream.

Corrosion, particularly with high-sulphur fuels, usually is most noticeable at the cold end of the economizer. Good practice dictates tube temperatures not lower than 180° F. for steel tube economizers, and higher if sulphur is excessive. Cast-iron economizers were first used because of their low corrosion, but the greater safety and higher conductance of the steel tube economizer more than offsets its greater liability to corrosion.

Internal Corrosion will be negligible if oxygen or air in solution in feedwater be eliminated. In steel tube economizers, maximum allowable oxygen content is 0.025 c.c. per liter for 180° F. feed or above. This feed temperature, with oxygen limited as above, prevents internal corrosion, and tube temperatures also are high enough to prevent external corrosion, unless sulphur in the flue gas is excessive.

Cleaning.—Dust or soot deposits on cast-iron tubes usually are removed by mechanically-operated scrapers. Soot blowers are used extensively for cleaning the gas side of steel tube economizers. A method, sometimes used consists in washing the tubes by water, delivered over the top of the tube bank, running down by gravity, flushing all outside deposits.

DEAERATION AND DEACTIVATION OF FEEDWATER.—To prevent internal corrosion, dissolved gases in feedwater must be removed before it is fed to economizer or boiler. Deaeration, or liberation of gases by boiling the water, and deactivation, or absorption of gases by a chemical reagent, such as iron turnings, are processes effecting this result.

In a typical deaerator, the water is heated to saturation temperature, thus removing gases from solution. Further agitation, which may be effected by steam jets or by ebullition of the liquid itself, separates the entrained gases, which then are vented from the apparatus. The Elliott deaerator, operating with an open heater temperature of 210° F., and a separator temperature of 188° F., will deliver water with a gas content not exceeding 0.02 c.c. per liter.

In the usual type of deactivator, the water, heated by external means, passes to a closed chamber filled with iron turnings, or thin perforated plates, of any rapid deactivating material. Oxygen and free gases are absorbed, the rate depending primarily on feedwater temperature. A combination deaerator and deactivator often is used where feed temperature is below 200° F. and water free of gases is desired.

An open feedwater heater, properly vented, with feed temperature of 210–212° F. will reduce the oxygen content to approximately 0.2 c.c. per liter.

3. AIR HEATERS

The purpose of the air heater is to extract additional heat from the gases of combustion leaving the economizer, and to raise the temperature of air used for combustion, for drying or other purposes. Gas exit temperatures from the economizer may be excessive if inlet feedwater temperatures are high, and the use of an air heater is necessary for the most economical production of steam. The fact that considerable duct length for gases and air is required, and that air leakage or gas infiltration, if excessive, is harmful, impose problems of design and arrangement that require considerable study.

TYPES OF AIR HEATERS.—Air heaters may be classed as tubular, plate and regenerative.

Tubular Air Heater.—Gas usually flows through the tubes and air passes across and in the opposite direction outside of them. Fig. 15 shows a tubular air heater designed for use with boilers fired by any fuel. A nest of steel tubes is expanded into upper and lower tube plates, and enclosed in a rectangular steel casing, which is the air flue. Provision is made for the expansion of tubes with reference to the casing. Inlet and outlet openings for air and gas are provided. Deflecting baffles are arranged to distribute air evenly over the outside of the tubes with minimum resistance. This type of air heater is inherently tight and maintains separation of air and gas streams.

Plate Type Air Heaters consist essentially of a casing, divided into a series of thin narrow compartments by metal partitions. Gas and air pass through alternate spaces in opposite directions. The large area of joints imposes leakage problems of considerable magnitude.

Regenerative Type Air Heaters consist of rotating plate elements that alternately absorb heat from the gas and transfer it to the air. The elements are not conducting partitions, but are mediums for temporary heat storage, and must move from the gas duct to the air passage.

ADVANTAGES OF USING HEATED AIR.—The heat abstracted from the gases and returned to the system is not absorbed by the working fluid (water or steam) but by air for the furnace. The economies effected are due to the release of this heat in the

furnace and its absorption by the heating surface. The increased temperature of combustion air accelerates combustion, and a smaller furnace volume may be used, or for a given volume, greater capacity for heat release is available. The heat released per pound of fuel by combustion, and the resulting temperature rise being the same under identical conditions, furnace temperatures will be higher with hot air than with cold. Raising furnace temperature will increase the difference between the temperature of hot solids and gases in the furnace and that of surfaces exposed to the furnace. The absorption of furnace heat and the temperature of furnace exit gases are increased over what they would be without preheated air, resulting in increased heat-absorbing capacity per square foot of gas-swept surface between furnace and air heater. Efficiency also increases because of lower unconsumed combustible losses.

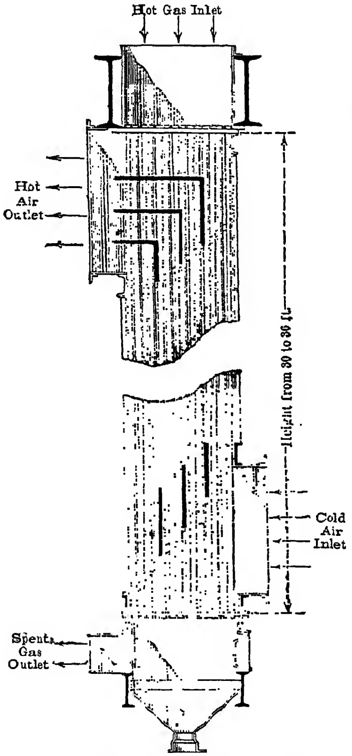

Fig. 15. Babcock & Wilcox Tubular Air Heater

HEATING SURFACE.—Air heater surface costs much less per square foot than boiler or economizer surface. The air heater is not subject to steam pressure, and can be of lighter construction, with less regard to trouble from leaky joints. The maximum difference in pressure between air and gas passages, resulting from induced draft on the gas side and forced draft pressure on the air side, normally does not exceed 0.75 lb. per sq. in. Air heater surface installed, in connection with boilers and economizers, usually is from 80 to 150% of boiler heating surface. Without economizers it may be as high as 300%. With steaming economizers, the maximum amount of air heater surface may approximate 900% of boiler heating surface.

TRANSFER RATE.—The rate of heat transfer of air heater surface is less than that of economizer or boiler surface, because air offers greater thermal resistance, on the receiving side of the surface, than does the boiler. While form of gas and air passages has some effect on the rate of heat transfer, it depends primarily on gas and air velocities. Draft loss increases with velocity. Hence velocity, and also transfer rate, is limited by the allowable draft loss through the heater. Heat transfer rates for air heaters vary between 2.5 and 4 B.t.u. per hr. per sq. ft. per deg. mean temperature difference between gas and air. For every installation there is some velocity beyond which the power necessary to provide draft offsets any gain in efficiency effected by the heater.

ALLOWABLE AIR TEMPERATURES.—In air heaters, built of ordinary carbon steel, metal temperature should not exceed 900° F. This limit can be raised by using alloy steels, as KA2, or by calorizing the carbon steels. Temperatures of preheated air for combustion vary widely. For fuels burned in suspension (pulverized coal, oil, gas) maximum air temperatures used are about 600° F., but the extreme temperature, with a properly cooled furnace, is that which the metal of the air heater can withstand. In pulverized coal firing, secondary air may approach 600° F. The temperature of primary air may be limited by mills or burners, and usually approximates 225° F., depending primarily on the moisture content of the coal. In stoker firing, maximum allowable air temperature varies from 350° F. with chain-grate stokers to 450–500° F. with underfeed stokers.

HEAT ABSTRACTED BY AIR HEATER.—The exit gas temperature from the air heater usually chosen is that which is most economical for operation of the particular unit. The exit air temperature is based on the requirements or limitations of the furnace and burner or stoker. With constant inlet air temperature, final temperature limits for exit air and exit gas determine the amount of heat that can be abstracted and returned.

and the temperature at which gases must enter the air heater. The position of the air heater, between furnace and stack, is fixed by inlet gas temperature, which in turn depends on the heating surface in advance of the air heater. This limitation of gas temperature at the air heater entrance, often renders advisable a small economizer between air heater and boiler as a means of adjusting gas temperature, to avoid additional heating surface in the boiler. The weight of the gas passing through an air heater is greater than the weight of the air. This causes a loss which increases with the temperature to which the air is heated. The loss is reduced by the use of an economizer, and there is a certain ratio of economizer and air heater surface that will give the best results.

OVERALL EFFICIENCY VS. LOAD VARIATIONS.—Load variations cause variations in exit gas temperature. The more gas temperature is lowered by the air heater the less it will vary with load. Overall efficiency of boilers with air heaters will vary less with load than boilers without them. With widely variable plant load this tends to keep average efficiency high. Air temperature necessarily increases with load.

CORROSION AND CLEANING.—Corrosion occurs only on the gas side of air heaters, and may be limited by keeping gas temperature above the dew point. With high-sulphur fuels, the temperature limit must be raised, to avoid all possibility of the condensation of moisture containing SO_2 on the heater surfaces.

Air leakage into the stream of hot gases cools the gases locally, impairs heating capacity, and necessitates a compensating increase in fan power to handle the excess flue gas. Leakage is minimized by good design, and is least for tubular types.

Air heaters in which gases pass over the tubes may be cleaned by mechanical soot blowers, or washed with water. A turbine cleaner is used with those heaters in which gas passes through the tubes.

CALCULATION OF SURFACE REQUIRED.—The relation between heat absorbed by the air and heat given up by gases of combustion is

$$AUT = Wc(t_1 - t_2) \qquad \text{or} \qquad AUT = W_1 c_1(T_1 - T_2)$$
$$A = H_a/UT \qquad \text{or} \qquad A = H_g/UT$$

where A = area of air heater surface, sq. ft.; U = conductance, B.t.u. per hr. per sq. ft. per degree mean temperature difference; T = logarithmic mean temperature difference between air and gases of combustion; W, W_1 = respectively, weight of gases and air passing through heater, lb. per hr.; H_a, H_g = respectively, heat absorbed by air and released by gases, B.t.u. per hr.; c, c_1 = respectively, mean specific heats of gases and air; t_1, t_2 = respectively, temperatures of entering and leaving gases, deg. F.; T_1, T_2 = respectively, temperatures of leaving and entering air, deg. F.

$$T = \frac{(\text{Maximum temperature difference}) - (\text{Minimum temperature difference})}{\log_e\{(\text{Maximum temperature difference})/(\text{Minimum temperature difference})\}}$$

Since the gas outlet from a boiler or economizer usually is the full width of the setting, and floor space is at a premium, air heaters generally are equal in width to the setting, and narrow in direction of the depth. An additional advantage is the ease of fluid entrance, and in a tubular air heater, as Fig. 15, air resistance is low by reason of fewer number of tube rows crossed. The relation of width to length determines the proportions of the surface in effective counterflow relations.

Air heater surface required for various temperature drops for a 2 1/2-in. O.D. tubular counterflow air heater containing 1500 tubes, under the operating conditions stated are:

Gas temperature drop, deg. F.	100	200	300	400
Sq. ft. external tube surface	6,010	15,280	31,750	70,500
Approximate length of tubes, ft.	6	16	32	72
Exit air temperature, deg. F.	205	329	451	573

Conditions: Gas, 350,000 lb. per hr., entering at 700° F.; gas mass flow, 7840 lb. per hr. per sq. ft. of free flow area. Air, 300,000 lb. per hr., entering at 80° F.; air mass flow, 6730 lb. per hr. per sq. ft. of free flow area.

Because of the excessive tube length of 72 ft. required for a 400° F. drop in gas temperature, the heater would be made in two sections in series, each with tubes 36 ft. long, with common upper and lower tube sheets. Gas flows down through one section and up through the other. A central partition extending from the upper tube sheet to the common passage between sections separates the air in the two sections. The counterflow principle is preserved. Gas draft loss for the two sections under the above conditions, is approximately 4.8 in. of water, and air resistance approximately 4.4 in. Increasing the section of the heater will reduce draft loss almost directly as the square of the number of tubes, since the length of the heater will be decreased only slightly by reduced air and gas conductances.

UTILIZATION OF WASTE HEAT

Waste gases from many types of industrial furnaces are discharged at high temperature and may profitably be utilized for generating steam in waste heat boilers. Such installations may be classified generally as: 1. Those operating with practically constant gas temperatures and weights. 2. Those in which, due to furnace operation cycles, gas temperatures and weights vary over a considerable range. See Table 1 for types of industrial furnaces supplying gas to waste heat boilers, and the gas temperatures in each class of work, according to former standard practice. Many furnaces of recent design for these and other purposes operate with lower exit gas temperatures, due to improvements in design, including air preheating by recuperators and regenerators for high temperatures. For these special cases, reference should be made to other sources. Temperatures shown represent average values over a complete cycle of furnace operation.

Exhaust gases from internal combustion engines also may be sources of heat for steam boilers. No generalization as to gas temperatures is feasible, since it depends on mean pressures in the engine cylinder. Mean pressure varies widely, and is lower for 2-cycle engines with scavenging air than for 4-cycle engines.

TREND IN WASTE HEAT BOILER DESIGN.—Installations prior to 1915 were for use with high temperature gases, and depended on natural draft. Non-interference with operation of the furnace was the prime requisite in design. As ample draft at the industrial furnace was the only indication of non-interference, waste heat boilers receiving gases from the furnace were installed to operate with low gas velocities, and consequent minimum draft resistance. Baffles usually were omitted, and high exit gas temperatures from the boiler were common and considered desirable for increasing draft produced by the chimney. Operation of waste heat boilers with any but high temperature waste gases was not economically practicable. See p. 6-09 for typical designs of waste heat boilers.

Since 1915, the use of mechanical draft has made available gas velocities much higher than were common in former practice, exceeding those usually found in direct-fired boilers. High gas velocities result in high rates of heat transfer by convection. This is desirable in waste heat boilers to offset lack of heat transferred by radiation. That part of the boiler exposed to a furnace temperature of 2800° F. (direct-fired) will absorb approximately 14 times more heat by radiation than will a boiler exposed to a furnace temperature of 1200° F. (waste heat practice). With entering waste gas temperatures of 1200–1300° F., and the boiler developing rated capacity, average velocity is about 2500 ft. per min. through the setting, or almost four times the velocity needed to develop rated capacity in a similar direct-fired boiler. If initial gas temperature is lowered, gas velocity must be increased to maintain the same heat transfer rate. With a definite initial gas temperature, boiler capacity is limited by the maximum gas velocity that can be obtained with available gas producing equipment.

High draft loss through modern (1935) waste heat boilers, together with reduction in exit gas temperatures from the boiler, preclude dependence on natural draft stacks alone, and require installation of induced draft fans. The adoption of fans, not used by furnace operators before 1915, has given better control of draft at the primary furnace. With excess draft usually available, furnace operations have been improved, and, in many cases, industrial output increased. Turbine-driven fans, primarily used because most of the power required to drive them was recovered from heat in the exhaust steam, are

Table 1.—Temperatures of Waste Gas from Industrial Furnaces

Type of Primary Furnace	Temperature, deg. F.
Nickel refining furnace	2500–3000
Beehive coke ovens	1950–2300
Black liquor furnace	1800–2000
Zinc refining furnace	1700–2000

Open-hearth steel furnace (Producer-gas-fired)	1200–1300
Open-hearth steel furnace (Oil, tar, or natural gas)	800–1100
Gas benches	1050–1150
Oil stills	900–1000
Glass tanks	800–1000

* During operating periods. With furnace kept hot but heating no material, average temperature 1000–1100° F.

† Average over 36-hr. cycle; range 500–2100° F.

susceptible to changes in steam pressure, which affects the flow of gases through the boiler. The tendency in recent years has been to use electric motors for the fan drive.

Waste heat boilers may be of the water-tube or fire-tube type. Consideration must be given to the avoidance of dirt accumulations, and for this reason, vertical tubes predominate in fire-tube boilers because of their greater ability to shed dirt. High gas velocities are utilized to scour the tubes, this being at the expense of draft loss. Waste gases at pressures of several atmospheres sometimes are used. Casing then must be designed to be gas tight, to avoid the hazards of inflammable or toxic gases.

USE OF ECONOMIZERS WITH WASTE HEAT BOILERS.—Economizer heating surface in waste heat work usually is 35 to 40% of the boiler heating surface, which is much less than in direct-fired practice. The high ratio of gas weight to water weight in waste heat economizer practice makes this reduction possible. In direct-fired practice, rise in feedwater temperature through the economizer is, roughly, 1° F. for each 2° F. drop in gas temperature; in waste heat practice 1° F. rise in feedwater temperature results in approximately 1° F. drop in gas temperature. This makes possible, with economizers in waste heat work, an increase in feedwater temperature greatly in excess of that which may be obtained with an equal amount of economizer surface in direct-fired practice, despite low gas temperatures from the waste heat boiler.

CLEANING.—Gases used in waste heat boilers are invariably dirty. With proper arrangement of dusting apparatus, soot pockets, and in some installations, dust conveying systems, boilers, economizers and flues can be kept as clean as in direct-fired work. Dust-conveying systems are used when dust has a reclaimable value.

TYPICAL TEST RESULTS.—Table 2 shows results which have been obtained with waste heat boilers in connection with various industrial furnaces.

Table 2.—Tests of Waste Heat Boilers *

	Type of Industrial Furnace				
	Beehive Coke Ovens	Heating Furnace	Cement Kiln	Open-hearth Steel Furnace	Glass Tanks

MOISTURE IN STEAM

1. STEAM CALORIMETERS

Moisture in steam is caused principally by high concentration of total solids, and other impurities (see p. 6–65), in the boiler water, resulting in foaming and priming. In boiler tests it is necessary to determine whether the steam as generated is wet, saturated, or superheated. To ascertain the quality of wet steam, a throttling or a separating calorimeter, or a combination of the two generally is used. The barrel calorimeter, one of the early types, has been abandoned as inaccurate, except at very high pressure or low moisture. Under these conditions the conductivity method should be used.

THROTTLING CALORIMETER.—In the simplest throttling calorimeter, steam is drawn from the main by a sampling pipe and throttled through a small orifice into a chamber, fitted with a thermometer well, a cock for pressure manometer attachment, and a comparatively large exhaust opening, closed by a valve. Some calorimeters are open to atmosphere on the exhaust side, the exhaust valve and manometer attachment being eliminated. The instrument, and all pipes and fittings leading to it, should be thoroughly insulated to diminish radiation losses. The only observations required are temperature and pressure of steam in the calorimeter chamber, and pressure of steam in the main. The range of moisture determination of the throttling calorimeter is limited, but it increases with higher pressures up to 400 lb. per sq. in. abs., where the limiting moisture content

of the steam is about 7%. At very low pressures, steam must be practically dry if the calorimeter is to operate satisfactorily. If the chamber of the calorimeter is connected to a condenser the range may be extended.

A simple form of throttling calorimeter is shown in Fig. 1. Two concentric metal cylinders are screwed to a cap containing a thermometer well. Steam pressure is measured by a gage connected to the supply pipe. Steam passes through orifice *A* and expands to atmospheric pressure, its temperature at this pressure being measured by thermometer *C*. Radiation losses are reduced by using the annular space *D* as a jacket to which steam is supplied through hole *B*.

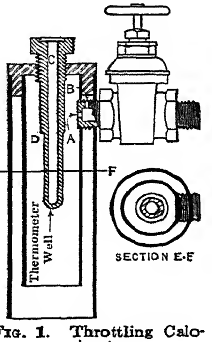

Fig. 1. Throttling Calorimeter

The principal source of error in steam calorimeter determinations is failure to obtain an average sample of steam. The type of steam sampling nozzle and its location is, therefore, extremely important. The A.S.M.E. Power Test Code recommends a 1/4- or 3/8-in. brass pipe, preferably the smaller, the portion projecting into the main being drilled in a straight line with 1/8-in. holes, as shown in Fig. 2 and Table 1. The end projecting within the main should extend to within 1/2 in. of opposite side of the steam main. The nozzle is installed in the line, with the holes directly facing the steam flow, preferably in a pipe where steam flow is downward, and as far removed from any disturbing element, as a valve or elbow, as possible. The next best location is in a pipe wherein flow is vertically upwards, other conditions being as before. A pipe in which steam ascends usually will show greater moisture, with the same sampling nozzle, than one in which steam descends. Pipe bends and horizontal pipes should be avoided as sampling nozzle locations.

EQUATION FOR DETERMINING MOISTURE IN STEAM.—Let p_1, p_2 = respectively, pressure in main and in calorimeter, lb. per sq. in., abs.; h_1, H_1 = respectively, heat of vaporization and total heat of steam corresponding to pressure p_1, B.t.u. per lb.; H_2 = total heat of saturated steam corresponding to p_2, B.t.u. per lb.; t_2 = temperature of saturated steam corresponding to p_2, deg. F.; t_c = temperature in calorimeter, deg. F.; c_p = specific heat of superheated steam in temperature range t_2 to t_c (assume 0.47 for approximately atmospheric pressures existing in calorimeter); Y_1 = percentage moisture in steam, by weight, at pressure p_1. Then

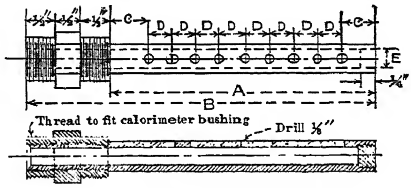

Fig. 2. Sampling Nozzle

$$- H_2 - 0.47(t_c - t_2)\}/h_1$$

Table 1.—Steam Sampling Nozzles for Pressures Above Atmospheric Pressure

Nominal Size of Steam Main, in.	Internal Diameter, in.	Holes in Nozzle		Dimensions, in. See Fig. 2				
		No.	Diam., in.	*A*	*B*	*C*	*D*	Pipe Size of Nozzle, in. *E*
2	1.939	3	1/8	1 3/4	3 1/4	5/8	1/2	1/4

16	14.75	8	1/8	14 1/4	15 3/4	1 1/2	1 7/8	3/8
18	16.5	8	1/8	16	17 1/2	1 7/16	1 7/8	3/8
20	18.5	9	1/8	18	19 1/2	1	2	3/8

Almost invariably the calorimeter exhausts to atmosphere. Then $H_2 = 1150.2$ and $t_2 = 212$, and

$$Y_1 = 100\{H_1 - 1150.2 - 0.47(t_c - 212)\}/h_1.$$

Moisture content may be determined by the total heat-entropy chart. Since in throttling, total heat remains the same it is only necessary to locate the point on the chart corresponding to conditions in the calorimeter (p_2 and t_c), and follow a constant total heat line until it intersects a constant pressure line corresponding to pressure in the main (p_1). Quality then can be read directly from the chart, and percentage of moisture by weight is (1 − quality reading from chart) × 100.

Correction for Radiation.—Loss from radiation will result in the temperature in calorimeter chamber being low. This temperature reading is corrected as follows:

The boiler is run at low load with low concentration, in order to obtain dry steam, at the pressure expected during the test. When observed temperature in the calorimeter becomes constant, the difference between this temperature and that of dry saturated steam, throttled to calorimeter pressure is the correction to be added to the all subsequent calorimeter temperature readings. No change then should be made in calorimeter installation or thermometer, until actual boiler test is completed.

EXAMPLE: At 160 lb. gage pressure, theoretical temperature of dry saturated steam when throttled to atmospheric pressure is 308° F. Assume normal reading to be 304° F. $(308 - 304) = 4°$ = radiation correction factor (including thermometer correction), to be added to all calorimeter temperature readings taken during test.

SEPARATING CALORIMETER.—Steam enters a separation device, consisting essentially of a perforated cup. Moisture is thrown out and deposited in a separating chamber, while the dry steam passes up and out of the separating device, through an annular steam jacket surrounding the separating chamber. The dry steam discharges through an orifice. Its total amount may be determined by condensing and weighing, or by calculating the flow by Napier's formula (see p. 16–53), providing size of orifice is known. The amount of moisture deposited in the separating chamber can be read directly from a water glass graduated in $^1/_{100}$ lb. While the accuracy of this calorimeter is less than that of the throttling type, it has a much wider range. The percentage of moisture by weight is $Y = 100\,w/(W + w)$, where Y = percentage of moisture, by weight; w = weight of moisture collected in separating chamber, lb.; W = weight of dry steam condensed after passing through calorimeter, or weight as calculated from flow formula, lb. If well insulated with hair felt, the radiation loss is known to be less than 0.05%.

THE UNIVERSAL CALORIMETER consists of a separating and throttling calorimeter, of high and low range, respectively, in series. Let Y_1 = percentage of moisture, by weight, in steam as determined by combination calorimeter; w_1 = weight of moisture collected in separating calorimeter in a given time, lb.; w_2 = weight of dry steam condensed after passing through the throttling calorimeter, lb.; Y_2 = proportion, by weight, of moisture in steam discharged from separating portion as determined by throttling calorimeter. Then, without radiation losses, $Y_1 = \{(w_1 + w_2 Y_2)/(w_1 + w_2)\} \times 100$.

THE SUPERHEATING CALORIMETER consists of a device where steam flows through a pipe which is jacketed with superheated steam, of sufficiently high temperature to superheat the steam sample. Moisture in sample taken from steam main may be determined by a heat balance between heat absorbed by sample and that lost by steam in the jacket.

THE ELECTRIC CALORIMETER is a form of superheating calorimeter. Steam from sampling nozzle enters the bottom of the calorimeter, passes upwards over heating coils, and thence to atmosphere. To determine moisture content, it is necessary to know the electrical input, temperature of exhaust steam, and the formulas and constants determined by the manufacturer of the apparatus.

CONDUCTIVITY METHOD of determining moisture and solids concentration in the steam consists of obtaining simultaneous samples of steam condensate (having a minimum of CO_2) and boiler water, both being cooled to approximately 77° F. from which the following data are obtained:

Conductivity of steam condensate; conductivity of 1% solution of boiler water in steam condensate; temperature of these samples; solids in the boiler water. From these data the parts per million (P.p.m.) of solids in the steam may be calculated as follows:

$$\text{P.p.m} = \{(L_s - W_c)/S \times 100)\}\text{P.p.m. in boiler water.}$$

$$\text{Equivalent moisture in steam} = (L_s - W_c)/S,$$

where L_s = conductivity of steam condensate at standard temperature of 77° F.; W_c = total conductivity correction due to CO_2 in pure water; S = conductivity increase due to adding 1% boiler water to steam condensate, corrected to standard temperature. The apparatus required is rather elaborate and the procedure somewhat involved. For

details, see Estimation of Solids in Steam Conductivity, J. K. Rummel, Analytical Ed. *Ind. and Engg. Chem.*, July 15, 1931.

2. STEAM SEPARATORS

STEAM SEPARATORS may be classified as gravity and inertia types. In the gravity type the velocity of steam is low enough to allow particles of moisture to fall through the flowing stream. In the inertia type, the velocity is high enough to project the particles of moisture on to collecting surfaces, from which they may drain. Inertia separators may be classed as single stream and subdivided stream separators, depending on their construction.

Boiler Drum Separators.—Separation of moisture from steam delivered from boilers may be done either in the boiler drum or in external separators. The oldest and commonest types of steam drum separator are the vertical baffle plate, which separates the steam space into two sections, the dry-pipe, and the dry-pan. The vertical baffle plate is sealed at the bottom by the water in the drum. Steam and moisture discharged from the boiler tubes is received in one section of the drum. The baffle restricts turbulence

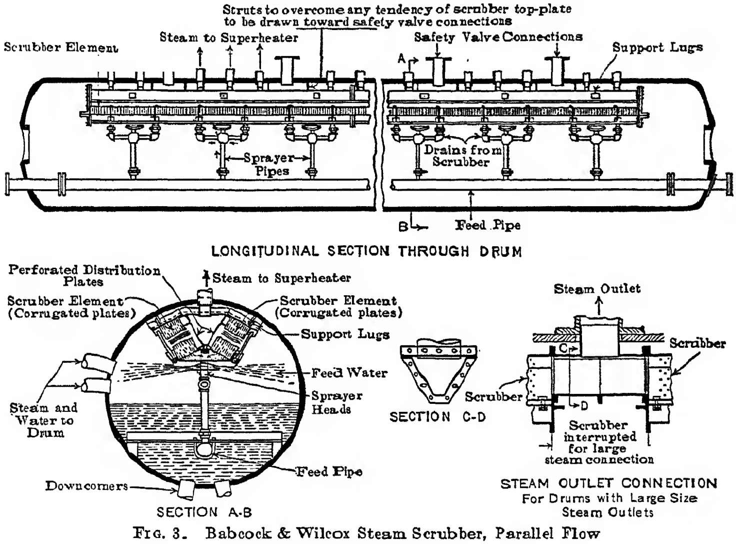

Fig. 3. Babcock & Wilcox Steam Scrubber, Parallel Flow

caused by the entrance of steam and moisture to the first section. Steam leaves the other section in a relatively quiescent state. Steam discharged from the turbulent section, after most of the water has been separated in the upper section, flows endwise to the extreme ends of the drum, around the baffle, and continues at relatively slow velocity in the quiet section to the steam outlet. This arrangement is reasonably satisfactory, providing the velocity of flow is low enough to permit the drops to fall by gravity against the current.

The latest arrangement (1935) of low-velocity steam separator uses a multiplicity of corrugated plates, offering relatively large surface for collecting moisture as the steam changes directions through the corrugated passages. Combined with this steam scrubber arrangement, steam sometimes is washed with the relatively clean boiler feedwater, delivered between sections of the series type, or before the sections of the parallel type of the steam scrubber, thus diluting impurities in the water comprising moisture in the steam, without adding to its total moisture content.

PERFORMANCE OF STEAM SEPARATORS.—The quality of steam which may be produced will vary over a considerable range, depending on type of boiler, boiler water concentrations, service conditions and type of separator used. In general, modern boilers

will deliver steam containing not more than 0.5% moisture, and often not more than 0.25% moisture. With proper control of boiler water concentrations and more efficient steam separators, moisture content may be zero as measured by steam calorimeter and it is necessary to resort to the conductivity method (see J. K. Rummel, Anal. Ed. *Indust. & Engg. Chem.*, pp. 317–320, July 15, 1931) which gives a measure of solids and equivalent moisture in the steam. It has been shown that with suitable equipment the steam may contain not more than one part per million of solids and not more than 0.1% equivalent moisture.

Fig. 3 shows the Babcock & Wilcox patented parallel-flow steam scrubber. Steam from the circulating tubes passes through a feedwater spray from sprayer heads and flows in parallel through both banks of corrugated elements, then through perforated distribution plates. It flows from the drum to the superheater through connecting tubes or a steam outlet connection. This scrubber is particularly suitable for high capacity with small size drums.

Fig. 4 shows a patented series flow steam scrubber. Steam from circulating tubes *a* passes through the first bank of corrugated elements *b* which removes the bulk of the entrained moisture, thence through the sheet of feedwater from the washer *d* and through

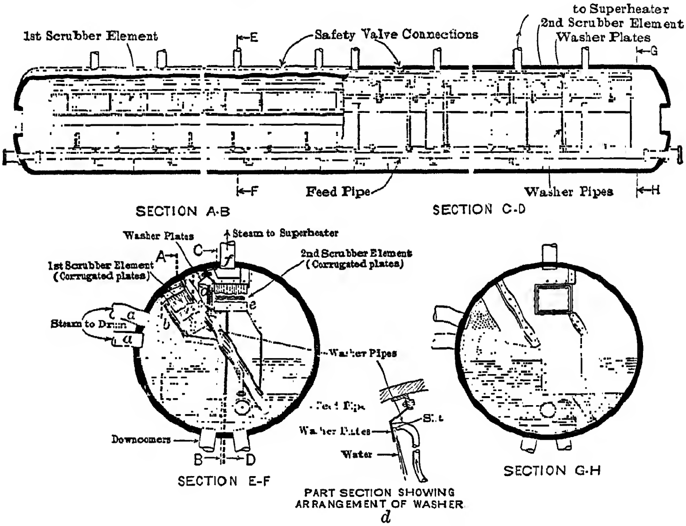

Fig. 4. Babcock & Wilcox Steam Scrubber, Series Flow

the second bank of corrugated elements to the steam space *e*, passing out of the drum to the superheater through tubes *f*. Closure plates at the ends of the scrubbers prevent steam from by-passing the corrugated elements. The following are results obtained with Babcock & Wilcox boilers with steam scrubbers installed.

	Plant A	Plant B
Boiler capacity, lb. per hr.	273,000	300,000
Steam pressure, lb. per sq. in.	1,400	625
Feed, type	100% condensate	100% make-up
Boiler water, concentration, parts per million	2,350	3,000
Solids in steam, parts per million	0.2	0.5
Equivalent moisture in steam less than	0.1%	0.1%

At plant A, with the original steam baffles in the boiler drums, the solids carry-over was at times sufficient to cause back pressure in the first stage of the high-pressure turbine to build up to 150 lb. per sq. in. after three or four days of operation. After installing the steam scrubber, operation for several months showed no increase in pressure, realizing a considerable saving in outage for cleaning.

BOILER FEEDING

1. THE INJECTOR

Principle of Operation of the Injector.—The simplest form of single-tube injector is shown in Fig. 1. Entering steam, in passing through the nozzle, acquires high velocity and is condensed by water in the combining tube. This creates a vacuum into which water flows through the water supply pipe. The high-velocity steam entering through *the nozzle, comprising a mixture of condensed steam and water, flows into the delivery* tube. There, the energy of steam expanding from boiler pressure to a partial vacuum produced by condensation, is sufficient to create pressure in the water as much as 50 to 80 lb. per sq. in. in excess of the boiler pressure, for the range of pressures in which the injector is used. This excess pressure forces the water into the boiler.

Equation of the Injector.—Let S = lb. of steam used; W = lb. of water lifted and forced into boiler; h = height, ft., of a column of water, equivalent to absolute pressure in boiler; h_0 = height, ft., that water is lifted to injector; t_1, t_2 = respectively temperature of water entering and leaving injector, deg. F.; H = heat content of steam supplied to injector, B.t.u. per lb., above 32° F.; L = work lost in friction and the equivalent lost work due to radiation and lost heat; 778 = mechanical equivalent of heat. Then

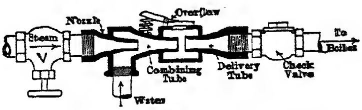

FIG. 1. Diagram of the Injector

$$S\{H - (t_2 - 32)\} = W(t_2 - t_1) + [\{(W + S)h + Wh_0 + L\} \div 778] \quad . \; . \; . \quad [1]$$

Neglecting $(Wh_0 + L)$,

$$S = [W(t_2 - t_1) + \{(W + S)/d\}\,p \times (144/778)]\,[1/\{H - (t_2 - 32)\}] \quad . \; . \quad [2]$$

or

$$S = W[(t_2 - t_1)d + 0.1851\,p] \div [\{H - (t_2 - 32)\}d - 0.1851\,p] \quad . \; . \; . \; . \quad [3]$$

where d = weight of 1 cu. ft. of water at temperature t_2; p = absolute pressure of steam, lb. per sq. in.

If in equation [1] the quantity $[\{(W + S)h + Wh_0 + L\} \div 778]$, which is the work of pumping, is assumed equal to zero, the equation takes the form

$$W/S = (H - t_2 + 32) \div (t_2 - t_1),$$

which is approximate and is analogous to that which Strickland Kneass (Theory of the Injector, p. 83) gives for the performance of an injector.

To find proper sectional area for narrowest part of the nozzle Rankine (Steam Engine, p. 477), gives

Area, sq. in. = (cu. ft. per hr. gross feedwater) ÷ ($800\sqrt{\text{pressure in atmospheres}}$).

Positive and Automatic Injectors.—Positive-type injectors have hand-controlled overflow valves, which are closed after operation has started and water appears in the overflow. The advantages of this type of injector are its ability to lift water to a greater height, to start with a lower steam temperature, and to discharge against a higher back pressure. In automatic injectors, opening and closing of the overflow is entirely automatic. This type is preferred for stationary work because of its restarting features.

THE INJECTOR AS A BOILER FEEDER is efficient and convenient. It has no moving parts, is compact, delivers hot water to the boiler without preheating, and has no exhaust steam to be disposed of. When used to feed water to a boiler, its thermal efficiency is 100%, less the trifling loss due to radiation, since all heat rejected passes into the water and is carried into the boiler. The loss of work in the injector, due to friction, reappears as heat which is carried into the boiler. The heat converted into useful work in the injector appears in the boiler as stored-up energy. Although the injector has perfect efficiency as a boiler feeder, it is not the most economical means of feeding because of its inability to handle hot water, thereby excluding the utilization of other sources of waste heat for boiler-feed heating. It also is difficult to maintain continuous flow with the injector at low capacity, because of the necessity of starting and stopping under such conditions. Furthermore, it cannot be operated with very high pressure steam due to the difficulty of efficiently operating a small nozzle under high pressure.

The injector has been widely used on locomotives but has been displaced in certain cases by direct-acting feed pumps, especially when feedwater heaters are used. It is limited in stationary work to small or single boilers, or as a reserve feeder. The injector used as a pump has an efficiency of approximately 1 to 2 percent. The weight of feedwater handled per pound of steam usually decreases as steam pressure increases, and varies between approximately 21 lb. at 20 lb. per sq. in. gage pressure to 10 lb. at 100 lb. pressure.

Maximum temperature of feedwater which can be handled will not vary widely with steam pressure, and averages from 120 to 140° F. at sea level, and lower at higher altitudes.

Table 1.—Test of Sellers Injector

From Practice and Theory of the Injector, by S. L. Kneass

Mean steam pressure, lb. per sq. in.	30	60	121	150	200
Temperature of supply water, deg. F.	67	67	54	54	50
Maximum capacity:					
Gallons water handled per hr.	1912	2535	3517	3765	4005
Temperature of delivered water, deg. F.	113	125	134	135	154
Weight of delivered water per lb. of steam used, lb.	25.9	19.1	13.6	12.6	10.3
Minimum capacity:					
Gallons water handled per hr.	765	937	1290	1432	1732
Temperature of delivered water, deg. F.	171	212	238	250	263
Ratio of minimum to maximum capacity	0.4	0.37	0.37	0.38	0.43

2. BOILER-FEED PUMPS

Pumps for boiler feeding are of two general classes: Direct-acting displacement pumps and centrifugal pumps.

RECIPROCATING PUMPS used as boiler-feed pumps usually are direct-acting duplex pumps. This type is essentially the same as two single pumps (direct-acting simplex) mounted side by side, with the piston rod of one actuating the variable gear of the other, and gives a practically continuous flow of water. Although the direct-acting simplex pump has lower first cost and maintenance, it delivers feedwater with a certain irregularity which may lead to strains in the feed piping.

Plungers are preferable to water pistons because of greater ease in adjustment, minimum slippage, and because all leakage is visible. The double plunger pump is equivalent to a piston. Steam consumption may be decreased by compound or triple-expansion steam ends, but this gain may be offset by increased initial and maintenance costs. Where exhaust is used for heating the feed there is little difference in plant efficiency.

The average direct-acting simplex or duplex boiler feed pump uses approximately 5% of the boiler steam, but if the pump exhaust is used to heat the feedwater, the net heat consumption is less than 0.1%. Direct-acting or duplex pumps for boiler feeding are, in general, used in the smaller plants because of their simplicity and reliability, it being possible to operate them even under water. See also p. 2–69.

CENTRIFUGAL PUMPS are almost universally used in medium and large size plants. They are built in two or more stages, depending on the pressure at which feedwater is to be delivered. Single-stage centrifugal pumps rarely are used for heads of over 250 ft.

Centrifugal pumps seldom are used in small plants because of the difficulty of building pumps of this type that will be efficient in small sizes, especially for high pressure work. As pressure increases, the minimum size of the pump increases, as does also back leakage.

Centrifugal pumps are continuous in action and do not set up pulsating strains in feed piping. Motor-driven multi-stage boiler-feed pumps may be operated at 3600 r.p.m., but 1750 r.p.m. is the usual speed. For larger pumps 1200 r.p.m. is used. Turbine-driven pumps may be operated at any desired speed, which may be varied in accordance with load conditions. This feature is not available in motor-driven pumps unless operated under direct current, or in connection with variable speed gear sets. Efficiencies as high as 87 to 88% have been realized under very favorable conditions, but for average size pumps handling about 1000 gal. per minute against 600 lb. pressure, an efficiency of 75 to 80% is considered good performance. See p. 2–83.

3. FEEDWATER HEATERS *

TYPES OF HEATERS.—While any device used to transmit heat to feedwater, prior to admitting this water to the boiler, may be called a feedwater heater, the term generally is applied to equipment using steam for heating. This equipment comprises two general classes: 1. Open, or direct contact, heaters, in which the steam comes directly in contact with the water. Tray type heaters and jet heaters form the two main sub-divisions of this class. 2. Closed heaters, in which the heat from the steam is transmitted through tubular metallic walls to the feedwater. Either open or closed heaters can utilize the exhaust from engines or pumps, or be used as stage heaters supplied with steam extracted from bleeder turbines.

SAVINGS OF FEEDWATER HEATERS.—Feedwater heaters, either open or closed, are useful in conserving the heat in pump or engine exhaust, high-pressure trap discharges, etc., which otherwise would be wasted. There is, roughly, a saving of 1 percent for every

* Contributed by J. S. Daugherty.

10° F. that the feedwater is heated. The saving effected by a heater may be determined from the formula $(h_2 - h_1)/(H - h_1)$, where h_1, h_2 = B.t.u. per pound of feedwater entering and leaving heater, respectively; H = B.t.u. per pound of steam at boiler pressure.

ELIMINATION OF STRAINS CAUSED BY COLD FEEDWATER.—A calculation in *The Locomotive*, March, 1893, shows that the injection of cold feedwater into a boiler will impose a stress of nearly 38,000 lb. per sq. in., on a strip of steel 10 in. long adjacent to the entrance of the feedwater pipe if no allowance is made for elasticity of adjoining sections of the boiler. Making allowance for such elasticity, however, it is quite probable that a stress of from 8000 to 10,000 lb. per sq. in. may be imposed by cold feedwater striking directly upon the plates. This stress, in addition to the normal stress due to steam pressure, will easily tax the girth seams beyond their elastic limit if the feed pipe discharges near them.

REMOVAL OF GASES FROM FEEDWATER.—Possibly of even greater importance than the fuel saving effected by the open heater is its ability to liberate and remove dissolved gases from feedwater. Gases cannot stay in solution when the water is heated to the boiling point. Consequently, water temperatures should be maintained as close as is practical to saturated steam temperatures, even to the extent of supplementing exhaust steam with reduced pressure live steam. The extent to which oxygen can be expelled by heating water in standard open heaters at atmospheric pressure is shown by the curve, Fig. 2, supplied by the Cochrane Corporation.

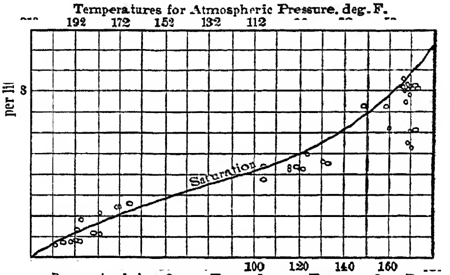

Fig. 2. Oxygen Content of Water from Standard Open Heaters

The deaerating feedwater heater, Fig. 2, has been developed from the older open heater. It is designed to accomplish practically complete removal of dissolved gases, of which oxygen is naturally the most objectionable. This is effected by heating the water exactly to the saturated steam temperature, spreading it in thin sheets over successive layers of air-separating trays, agitating it thoroughly so the gases may be brought to the surface and liberated, and sweeping the liberated gases

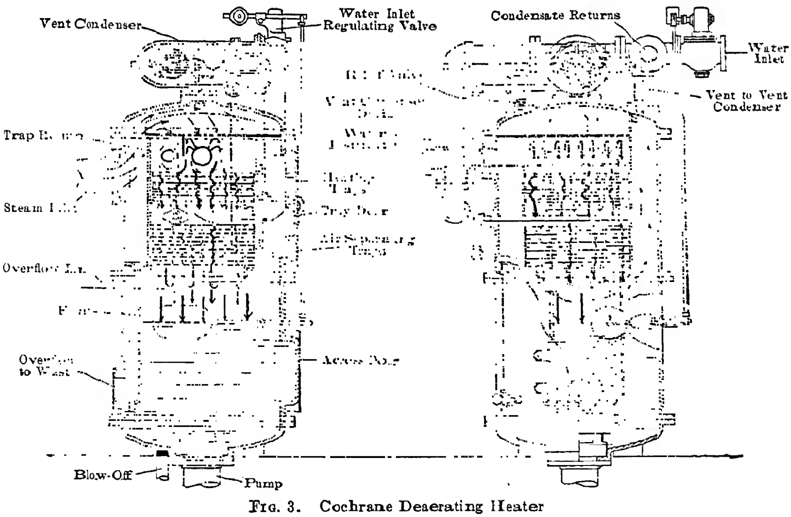

Fig. 3. Cochrane Deaerating Heater

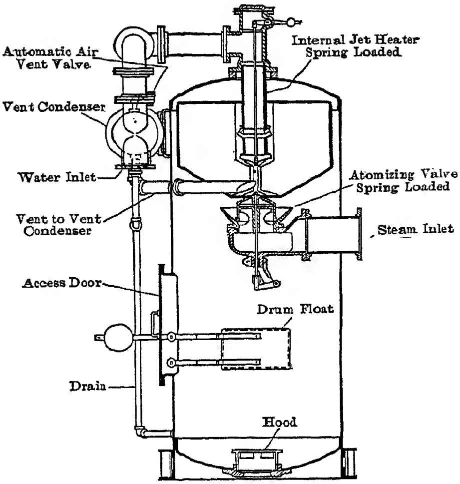

FIG. 4. Cochrane Deaerating Heater for Marine Service, Using Jets Instead of Trays

away with the steam vented to the vent condenser. Fig. 4 shows a deaerating heater for marine service, using jets instead of trays to give the same performance as the stationary deaerating heater.

CONSTRUCTION OF OPEN HEATERS.—When used for low pressures open heaters usually are constructed of cast iron. When supplied with superheated steam or used with steam extracted from bleeder turbines, the shells of tray type or jet type heaters are rolled plate, either riveted or welded.

PROPORTIONS OF OPEN TYPE FEEDWATER HEATERS.—The jet type open feedwater heater is of importance due to its ability to heat large quantities of water in a relatively small space. One large manufacturer offers a line of standard jet heaters with outlet capacities ranging from 100,000 lb. per hr. to 1,000,000 lb. per hr. in which the internal volume may be approximated from the formula,

$$V = W/10{,}000,$$

where V = internal volume, cu. ft.; W = outlet capacity, lb. per hr. The proportions of tray type open heaters are governed primarily by the particular conditions of operation and no general rule for these proportions is available. An approximation of the size of the heater may be made by having at least 1 sq. ft., in plan, of tray stack for each 15,000 lb. per hour capacity. Vertical units vary in height from about 4 ft. for small capacities to 10 ft. for larger capacities. About half the height is used for water distribution and the tray stack.

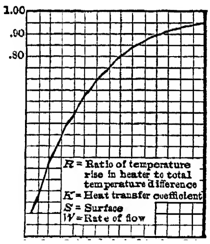

FIG. 5. Curve for Determining Surfaces of a Closed Heater

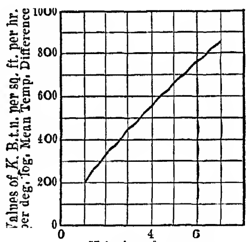

FIG. 6. Values of K

Water storage may be combined with open heaters. Where the feedwater is primarily all make-up and the load fluctuations are not severe, approximately two minutes boiler supply has been found sufficient. When the feedwater is condensate, with but a small amount of make-up, it often is the practice to incorporate condensate surge space in its storage compartment. The capacity for condensate surge varies from 5 minutes to 30 minutes supply for the boiler.

The location of an open feedwater heater in relation to the boiler feed pump is important. It must be at such an elevation above the pump inlet that the pump will receive only vapor-free liquid. The elevation will depend on temperature and pressure of water leaving the heater. Table 3, p. 2–67 gives data concerning the elevation of pumps handling hot water.

ADVANTAGES OF CLOSED FEEDWATER HEATERS.—Closed heaters in which steam does not come in contact with water but transmits its heat through tubular walls are quite important devices for heating service water for buildings and institutions, and for heating water for industrial processes, due to their ability to prevent the odor, taste, or impurities of the steam from being transmitted to the water being heated. The practical application of closed heaters to boiler feedwater heating service is limited to their inclusion as stage heaters in the regenerative feed heating cycle, which cycle should contain at least one direct contact feedwater heater. In the multi-stage regenerative feed heating cycle a multiplicity of feedwater pumps can be avoided by the use of closed heaters.

CALCULATIONS OF SURFACE OF CLOSED HEATERS.—The surface of a closed heater may be determined from the formula

$$S = (W \times T)/(K \times t_d)$$

where S = heat transfer surface, sq. ft.; W = lb. per hr. to be heated; T = temperature rise, deg. F.; K = heat transfer coefficient, B.t.u. per deg. F. logarithmic mean temperature difference per sq. ft. per hr.; t_d = logarithmic mean temperature difference, deg. F.

By using curve Fig. 5, developed by A. E. Kittredge of Cochrane Corporation, the surface of a closed heater also may be determined when the specific heat of the fluid is unity. In Fig. 5, R = Heating Ratio = (Temperature Rise)/(Max. Temp. Difference); K, S and W are as above. Values of K are influenced by velocity of fluid, fluid density, material of tube walls, etc. Conservative values are shown in Fig. 6.

FEEDWATER FOR STEAM BOILERS

1. COMPOSITION AND ANALYSIS OF FEEDWATER

IMPURITIES IN FEEDWATER.—Natural feedwater supplies contain solids and dissolved gases which may promote the following conditions in boilers: 1. Incrustation or scale. 2. Foaming, priming and solids in steam. 3. Corrosion. 4. Caustic embrittlement. To avoid these troubles, it generally is necessary to study each water supply individually and determine its individual characteristics and how it best may be treated.

Because of the high solids content, sea water and certain other bodies of water are unfit for use in boilers. Rain water becomes contaminated in falling through the atmosphere, and always contains dissolved gases, including oxygen and carbon dioxide. The latter forms a mild acid which greatly increases the solvent action of the water. Thus, with carbonic acid present, it can dissolve considerable amounts of such materials as calcium and magnesium salts from the ground through which the water passes.

It follows that waters from rivers, wells, and lakes will contain varying amounts of dissolved and suspended solids, depending on geologic formation, climate, vegetation, and pollution from various sources. Waters from mines where sulphates are present tend to be acid. Rivers and streams may become acid from industrial pollution, and sewage, sometimes present, produces objectionable decomposition products. Waters in rivers and streams often undergo rapid changes in dissolved and suspended solids, requiring close control of feedwater purification processes.

CLASSES OF IMPURITIES.—Table 1 is a partial list of impurities found in boiler feedwater, their effect in the boiler and the usual method of treatment. The solubilities are listed to show constituents which may be present in water, and whether they can be expected to precipitate under boiler operating conditions. Increase of temperature increases the solubility of some solids and precipitates others. Regardless of whether solubility increases or decreases with temperature, concentration of solids in the boiler water increases with continued evaporation. Table 2 gives the solubility of substances listed in Table 1. As solubilities vary with temperature and authorities differ on the values for some constituents, it is not possible to estimate all solubilities under boiler conditions. The important feature is the probable effect of these constituents in the boiler. See next to last column, Table 1.

The impurities may be roughly classified under the following headings:

Dissolved Gases.—Inert gases, as nitrogen and the hydrocarbons. Corrosive or active gases, as oxygen, carbon dioxide and hydrogen sulphide.

Dissolved Solids.—*Slightly Soluble Solids:* Includes most calcium and magnesium compounds. Also oil and silica.

Highly Soluble Solids: Includes all soluble salts, as sodium chloride, sodium sulphate, sodium carbonate, sodium nitrate and certain sodium silicates. Also sodium hydroxide, sodium phosphate, the acids and certain organic compounds.

Suspended Solids include the common clays and silts, organic and inorganic matter, found principally in rivers and streams, and all other insoluble matter.

Insoluble Liquids, oils, greases, soaps, etc., have a deleterious effect on boiler water.

Table 1.—Usual Impurities of Boiler Feedwater

Impurity	Formula	Molecular Weight	Equivalent Weigh	Solubility*	Probable Effect in Boiler	Methods of Treatment and Removal
Calcium Bicarbonate	$Ca(HCO_3)_2$	162.10	81.05	Moderate	Scale and sludge. Liberates CO_2	In external treatment of calcium and magnesium compounds, lime and soda softeners plus coagulation and filtration give partial removal. Zeolite softeners and evaporators give more complete removal, the former replacing calcium and magnesium with sodium. Corrosive compounds require alkali treatment. In internal treatment, calcium and magnesium are precipitated as hydroxide and carbonates by sodium hydroxide and sodium carbonate. Calcium, and sometimes part of the magnesium are changed to calcium and magnesium phosphates by treatment with sodium phosphates. Sodium hydroxide is preferred reagent for internal treatment of magnesium compounds. Calcium hydroxide is preferred for external treatment.
Calcium Carbonate	$CaCO_3$	100.08	50.04	Slight	Scale and sludge. Liberates CO_2	
Calcium Hydroxide	$Ca(OH)_2$	74.10	37.05		Scale and sludge	
Calcium Sulphate	$CaSO_4$	136.14	68.07	Moderate	Hard Scale	
Calcium Silicate	Variable	....	...	Slight	Hard Scale	
Calcium Chloride	$CaCl_2$	110.99	55.50	Very soluble	Corrosive. Scale and sludge	
Calcium Nitrate	$Ca(NO_3)_2$	164.10	82.05	Very soluble	Corrosive. Scale and sludge	
Magnesium Bicarbonate	$Mg(HCO_3)_2$	146.34	73.17	Moderate	Deposits. Liberates CO_2	
Magnesium Carbonate	$MgCO_3$	84.32	42.16	Slight	Deposits. Liberates CO_2	
Magnesium Hydroxide	$Mg(OH)_2$	58.34	29.17	Very slight	Deposits	
Magnesium Sulphate	$MgSO_4$	120.38	60.17	Very soluble	Corrosive, deposits	
Magnesium Silicate	Variable	....	...	Slight	Hard Scale	
Magnesium Chloride	$MgCl_2$	95.23	47.62	Very soluble	Corrosive, deposits	
Magnesium Nitrate	$Mg(NO_3)_2$	148.34	74.17	Very soluble	Corrosive, deposits	
Sodium Bicarbonate	$NaHCO_3$	84.00	42.00	Very soluble	Increases alkalinity and soluble solids. Liberates CO_2	
Sodium Carbonate		106.00	53.00	Very soluble	Increases alkalinity and soluble solids. Liberates CO_2	Excess sodium alkalinity may be reduced by boiler blowdown. It sometimes is neutralized with sulphuric acid externally. Phosphoric acid and acid phosphates also are used. Evaporation is best practical means of removing sodium compounds from feedwater. Boiler blow-down used for internal reduction of soluble solids.
Sodium Hydroxide	NaOH	40.00	40.00	Very soluble	Increases alkalinity and soluble solids.	
Sodium Sulphate		142.05	71.03	Very soluble	Inhibitor for caustic embrittlement. Increases soluble solids.	
Sodium Silicate	Variable			Very soluble	Increases alkalinity. May form silica scale	
Sodium Chloride		58.45	58.45	Very soluble	Increases soluble solids. Encourages corrosion.	
Sodium Nitrate	$NaNO_3$	85.01	85.01	Very soluble	Increases soluble solids.	
Iron Oxide	Fe_2O_3	159.68	26.61	Slight	Deposits. Encourages corrosion	Coagulation and filtration, evaporation, blowdown.
Alumina	Al_2O_3	101.94	16.94		May add to deposits	Coagulation and filtration, evaporation, blowdown.
Silica	SiO_2	60.06	30.03		Hard scale, acts as binder for deposits	Precipitation with aluminates, coagulation and filtration, evaporation, blowdown.
Dissolved Oxygen	O_2	32.00	16.00		Corrosive	Deaeration preferred.
Carbonic Acid or Dissolved CO_2	H_2CO_3	62.02	31.01	Very soluble	Retards hydrolysis of carbonates. Reduces alkalinity	Deaeration and alkali treatment.
Hydrogen Sulphide	H_2S	34.08	17.04	Very soluble	Corrosive	Deaeration and alkali treatment.
Acids, Organic & Mineral				Very soluble		Neutralization by alkali treatment.
Oil and Grease				Slight	Corrosive, deposits, foaming and priming	Coagulation and filtration, skimming.
Organic Matter				Very soluble	Corrosive, deposits, foaming and priming	Coagulation and filtration, evaporation.

*See Table 2.

SPECIFICATIONS FOR BOILER WATER AND FEEDWATER.—Perry Cassidy (Joint meeting of Engrs. Soc. Western Penna. and Pittsburgh Section A.S.M.E., Oct. 15, 1935) gives the following specifications as complying with what is practicable with present feedwater treatment methods and equipment:

Feedwater.—*Dissolved Oxygen.* Preferably zero and not over 0.05 cc. per liter for boilers; zero where steel tube economizers are used. *pH Value.* Not less than 7. Excess alkalinity other than required for treatment or protection of feed lines, or to neutralize acids, should be reduced to a minimum. *Hardness.* Preferably zero. Not over 26 parts per million in terms of calcium carbonate. *Chloride.* Lowest practical minimum is desired. When due to condenser or other leakage not over 6 parts per million in terms of chlorine. *Oil.* None. *Total Solids.* Reduce to minimum. *Suspended Solids.* None. *Organic Matter.* Not more than 5 parts per million.

Boiler Water.—*Sodium Phosphate.* With residual hardness in the make-up, 50 to 100 parts per million expressed as disodium phosphate. *Alkalinity.* Between 100 to 250 parts per million depending upon silicates which also are present. The higher alkalinity is preferred when silicate concentration is 100 to 200 parts per million. *Chlorides.* Not over 500 parts per million expressed as chlorine. Preferably as low as possible. *pH Value.* Not less than 10.5, preferably 11.0. *Sulphate-Carbonate Ratio.* See p. 6–75. *Oil.* None. *Total Solids.* Not over 1700 parts per million.

ANALYSES.—In examining raw water supplies to determine their suitability for feedwater and proper methods for purification, a complete analysis is preferred. When the purification plant has been standardized, control tests may be applied to feed and boiler water to maintain desired conditions. These usually consist of tests for: Alkalinity or acidity; pH value; hardness; chloride; sodium sulphate; dissolved oxygen; dissolved solids; turbidity.

Alkalinity or Acidity is measured quantitatively by a titration method, using a standard acid or alkali in a burette and flask containing sample and color indicator. If indicator shows an alkaline reaction, sample is titrated with the standard acid until a certain color end point is reached. If indicator shows an acid reaction, it is titrated with the standard alkali to a predetermined end point. Alkalinity or acidity is then calculated in parts per million or grains per gallon of the predominating alkali or acid.

***p*H Value (Hydrogen Ion Concentration)** is determined to measure the degree of acidity or alkalinity of a sample. The colorimetric method generally used consists of adding a measured amount of a chosen indicator to a measured volume of sample in a

test tube or small cell. The color of the tube is compared to sets of color standards which represent the result for different pH values. A useful universal indicator which can be used for both titration work and approximate pH value, can be obtained from laboratory supply houses, as Palo-Myers, Inc., New York.

Explanation of pH Value.—All aqueous solutions contain hydrogen (H) and hydroxyl (OH) ions. The product of their concentrations is equal to a constant value which at room temperature is approximately 1×10^{-14}. Neutral water contains an equal number of hydrogen and hydroxyl ions. The hydrogen ion concentration is, therefore, 1×10^{-7} grams of ionized hydrogen per liter.

When acid is added the hydrogen ion concentration increases with corresponding decrease in hydroxyl ion concentration. When an alkali is added the hydroxyl ion concentration increases, and the hydrogen ion concentration decreases. Since all acids and alkalies do not ionize alike, the quantity of acid or alkali does not give a direct measure of hydrogen ion concentration. Strong acids, as hydrochloric, and strong alkalies, as sodium hydroxide, are much more effective in changing hydrogen ion concentration than relatively weak materials, as carbonic acid and sodium carbonate.

For convenience, only the hydrogen ion concentration is recorded, whether the solution be acid or alkaline. Hydroxyl ion concentration may be found by dividing hydrogen ion concentration into 1×10^{-14}. Thus, if hydrogen ion concentration is 1×10^{-8} the hydroxyl ion is 1×10^{-6}. Hydrogen ion concentration is expressed in terms of pH value, equivalent to log (1/H ion concentration), that is, to the negative exponent. Thus if hydrogen ion concentration is 1×10^{-9}, pH value is 9. The lower the hydrogen ion concentration, the higher is pH value. In neutral water $p\text{H} = 7$; in water that is relatively ten times as alkaline $p\text{H} = 8$. If $p\text{H} = 6$ the water is relatively ten times as acid as at $p\text{H} = 7$. Table 3 shows hydrogen ion concentration, its equivalent pH value, and corresponding color of the universal indicator. Table 4 lists several indicators, their solution concentrations, and the color change for the pH range to which they apply.

This method of measuring acidity or alkalinity is useful in controlling corrosion and certain chemical reactions in treatment of feed and boiler water. For feedwater pH should be at least 7, and for boiler water at least 10.5. Fig. 1 shows relation between pH and solubility of iron in deaerated water.

Hardness.—For control purposes, total hardness is determined by adding standard soap solution to a bottle containing a measured amount of sample, shaking the bottle vigorously between additions of soap solution, the bottle lying on its side, until an unbroken lather is maintained for five minutes on the water surface. Volume of soap solution used is referred to a chart or multiplied by a factor. The result is expressed in parts per million, grains per gallon, or equivalent calcium carbonate.

Table 3.—Hydrogen Ion Concentration as Shown by Color Indicators

Hydrogen Ion Concentration, Gram-Mols per Liter *		pH		Color of Universal Indicator
1.0	10^{-0}	0		
0.1	10^{-1}	1	Acid Range	
0.01	10^{-2}	2		
0.001	10^{-3}	3		
0.000,1	10^{-4}	4		Red
0.000,01	10^{-5}	5		Pink
0.000,001	10^{-6}	6		Yellow
0.000,000,1	10^{-7}	7	Neutral	Greenish Yellow
				Green
0.000,000,01	10^{-8}	8	Alkaline Range	Blue
0.000,000,001	10^{-9}	9		Blue—Violet
0.000,000,000,1	10^{-10}	10		Purple
0.000,000,000,01	10^{-11}	11		
0.000,000,000,001	10^{-12}	12		
0.000,000,000,000,1	10^{-13}	13		
0.000,000,000,000,01	10^{-14}	14		

* For hydrogen ion 1 gram-mol = 1 gram, but for hydroxyl ion 1 gram-mol = 17 grams.

Table 4.—Colorimetric Indicator Solutions

Indicator	Concentration	pH Range	Color Change
Meta Cresol Purple	0.04%	1.2—2.8	Red—Yellow
Bromphenol Blue	.04	3.0—4.6	Yellow—Blue
Methyl Red	.02	4.4—6.0	Red—Yellow
Bromcresol Green	.04	4.0—5.6	Yellow—Blue
Bromcresol Purple	.04	5.2—6.8	Yellow—Purple
Bromthymol Blue	.04	6.0—7.6	Yellow—Blue
Phenol Red	.02	6.8—8.4	Yellow—Red
Cresol Red	.02	7.2—8.8	Yellow—Red
Thymol Blue	.04	8.0—9.6	Yellow—Blue
Phthalein Red	....	8.6—10.2	Yellow—Red
Tolyl Red	....	10.0—11.6	Red—Yellow
Parazo Orange	....	11.0—12.6	Yellow—Orange
Acyl Blue	....	12.0—13.6	Red—Blue

Actually, hardness consists of such materials as calcium and magnesium carbonate and bicarbonates, calcium and magnesium sulphates, and calcium and magnesium chlorides. These materials can be precipitated by boiling, and are known as temporary hardness. For example, the bicarbonates of calcium and magnesium are changed to carbonates, which are much less soluble. The remaining hardness is known as permanent hardness.

Chloride concentration is determined by titrating a measured volume of sample with standard silver nitrate solution, using potassium chromate as an indicator. The end point is indicated by a red coloration. The result is expressed in parts per million, grains per gallon of chlorine, or equivalent sodium chloride.

Equivalent Sodium Sulphate determination is useful in boiler water analyses. In control work, benzidine sulphate titration, or the turbidity method is used. The titration consists of adding an excess of benzidine sulphate to a measured sample of water. After standing, to allow complete precipitation of sulphate as benzidine sulphate, filter and wash precipitate. Titrate the precipitate with a standard sodium hydroxide solution, using phenolphthalein as the indicator.

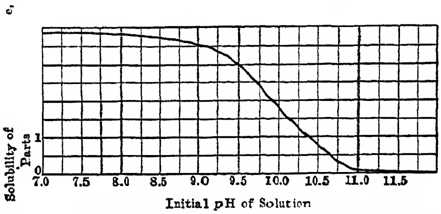

FIG. 1. Relation between *p*H and Solubility of Iron in Deaerated Water at Room Temperature

The turbidity method consists of adding hydrochloric acid and barium chloride to a measured sample of water, causing a white precipitate of barium sulphate to form. The sample is stirred to keep precipitate in suspension, and the mixture slowly poured into a graduated tube with a small light below it. When sufficient mixture has been added to just obscure the light filament, when looking down the tube, height of liquid is read, and equivalent sodium sulphate in parts per million or grains per gallon is estimated or read from the graduated tube.

Dissolved Oxygen is an important test in controlling deaeration of feedwater. It involves sampling water through a cooling coil to reduce temperature to below 70° F., flowing water from the coil through a glass-stoppered sample bottle to wash out any air not in the sample. The sample is then fixed with three reagents, usually manganous sulphate, alkaline potassium iodide, and sulphuric acid. A measured volume of the sample is titrated with a standard sodium thiosulphate solution, using starch as an indicator. If dissolved oxygen is absent there will be no blue coloration when the indicator is added. Result is expressed in cc. per liter or parts per million of dissolved oxygen.

Dissolved Solids may be estimated in several ways. In the laboratory they are determined by evaporating a measured volume of sample and weighing the dried residue. For boiler water, hydrometer, densimeter and conductivity tests are used, suitable calibrations being made for the type of water.

TURBIDITY tests are made by several methods, depending on the amount of suspended solids. For certain boiler waters containing considerable suspended matter, some type of turbidimeter may be used to regulate blow-down for suspended solids. The sulphate meter is operated by pouring liquid containing suspended matter into a tall glass cylinder until a light filament under the cylinder no longer is visible. Height of liquid in the cylinder is then read. Another method, for waters containing less suspended matter, involves the immersion of a graduated rod holding a wire at the end into the sample until the wire no longer can be seen.

2. TREATMENT OF FEEDWATER

CAUSES OF SCALE FORMATION.—Hard scale and incrustations of softer deposits result from the presence or formation of insoluble solids in feed and boiler water. Certain slightly soluble solids, when treated with water-softening chemicals, or heated and concentrated in the boiler water, become less soluble and precipitate. The most objectionable are calcium sulphate and silica, which have a strong tendency to crystallize and precipitate, forming hard scale which is difficult to remove. Both may act as a cement for other insoluble matter and hasten the formation of a sufficiently heavy scale, which, due to

its poor heat conductivity, will cause overheating and failures of boiler tubes. Calcium sulphate, and, to a slightly less extent, silica, tend to form scale on the hottest tubes. Calcium carbonate is somewhat more likely to precipitate in the boiler water than on the tubes. Its deposits tend to be greater in the cooler parts of the boiler. Due to external heating of feedwater containing calcium bicarbonate, the less soluble calcium carbonate often is formed and deposited in heaters and pipe lines. With this chemical present, the same result may be obtained by continuous addition of caustic soda to feedwater. Calcium phosphate tends to deposit in feed lines when sodium phosphate is used as a treating agent. Tannates have been used to delay precipitation of calcium compounds in the feed system. In general calcium phosphate does not give serious trouble in boiler water, but periodic cleaning is advisable.

For explanation of the process of scale formation see Hall, A Physico-Chemical Study of Scale Formation and Boiler Water Conditioning, Bull. 24, Carnegie Inst. of Tech., Pittsburgh, Pa.

SCALE PREVENTION.—No single method of treatment can be recommended which will apply to all feedwaters. In general, as much as possible of insoluble and slightly soluble material should be removed from feedwater without unduly increasing soluble solids. Any residual scale-forming material then should be treated in the boiler water to form non-adherent precipitates. Mechanical cleaning of the boilers should be performed as often as necessary to avoid trouble.

Methods of External Treatment

External treatments include coagulation and filtration, sedimentation of suspended matter, lime-soda treatment, zeolite treatment and evaporation. Combinations of some of these treatments often are desirable.

COAGULATION, SEDIMENTATION, AND FILTRATION may be used alone or in conjunction with lime-soda or other treatments. The removal of suspended matter is an important part of the treating system. Coagulation and sedimentation are carried on in large basins, or in tanks, depending on quantity of water to be handled. Usual coagulants are iron sulphate (copperas), aluminum sulphate, sodium aluminate, and lime. Cold water filtration is carried on usually with gravity or pressure-type sand filters. In hot-water filtration, less soluble materials, as calcite or magnetite, should be used to avoid formation of calcium silicate, which may result in hard, dense scale. Sand filters usually are designed for a capacity of from 2 to 4 gal. of water per min. per sq. ft. of cross-sectional area.

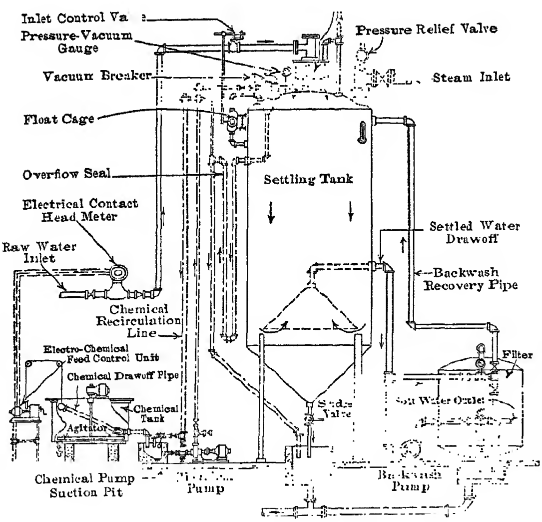

Fig. 2. Hot Lime Soda Water Softener (Permutit Co.)

LIME-SODA TREATMENT is applied in several ways, with considerable variation in design of equipment. The principal differences are in the temperature of water, cycle of operation (whether continuous or intermittent flow), and method of applying and agitating chemicals. Hot-process equipment usually consists of chemical mixing tanks, chemical proportioner (which introduces chemicals in proportion to flow of water), a deaerating type heater, placed above a reaction and settling tank, and a filter to remove unsettled suspended matter. The cycle usually is continuous. Water flows through

the heater into the top of the reaction and settling tank, where chemicals are introduced and thence to the bottom of the tank, where suspended matter settles and is blown out. The water then rises through a central duct and is discharged through the side of the tank, at a point below the water level. Treated water finally passes through a closed or pressure-type filter. Retention time of water in the tank is preferably not less than one hour.

In the cold process, equipment may be the same as in the hot process without the heater. Usually, it is desirable to have a longer reaction and settling time, and several treating tanks are provided. In these, water is treated, agitated, settled, and finally drawn off from the top to the filters. Each tank is treated in rotation. The cycle is so timed that treated water always flows from one tank to the filters while water in the others is being treated or settling. Filters frequently are of the open gravity type. Depending on analysis of raw water and excess of treating chemicals used, effluent water from a cold-process softener may have a hardness of from 2 to 5 grains per gal., or from the hot-process softener a hardness of from 1 to 3 grains per gal.

The chemicals used in these treatments are one or more coagulants (iron sulphate, aluminum sulphate, sodium aluminate), calcium hydroxide, and sodium carbonate. Coagulants are added either before or after lime and sodium carbonate, depending on the ease of coagulating suspended matter. Iron sulphate and aluminum sulphate both create acidity when added to neutral water, which must be corrected by alkaline chemicals. Sodium aluminate gives an alkaline reaction and besides being a coagulant for suspended matter, it has water-softening properties similar to that of sodium carbonate.

Calcium hydroxide or hydrated line combines with excess carbon dioxide, and reacts with calcium and magnesium bicarbonates to form less soluble calcium carbonate and magnesium hydroxide. Also when sodium carbonate is present, sodium hydroxide is formed. These reactions for lime are:

$2Ca(OH)_2$ Calcium hydroxide	$Mg(HCO_3)_2$ Magnesium bicarbonate	$2CaCO_3$ Calcium carbonate		$Mg(OH)_2 + 2H_2O$ Magnesium hydroxide
$Ca(OH)_2$ Calcium hydroxide	$Ca(HCO_3)_2$ Calcium bicarbonate	$2CaCO_3$ Calcium carbonate		
$Ca(OH)_2$ Calcium hydroxide	H_2CO_3 Carbonic acid	$CaCO_3$ Calcium carbonate		$2H_2O$
$Ca(OH)_2$ Calcium hydroxide	Na_2CO_3 Sodium carbonate	$CaCO_3$ Calcium carbonate	+	$2NaOH$ Sodium hydroxide

The principal use of sodium carbonate is to react with calcium sulphate to form a less objectionable scale-forming compound. Also, the treatment is effective in changing acid-forming salts to neutral salts. The resulting magnesium hydroxide and calcium carbonate are largely precipitated in the softener. The principal reactions are:

		$CaSO_4$ Calcium sulphate	+	Na_2CO_3 Sodium carbonate	=	Na_2SO_4 Sodium sulphate	+	$CaCO_3$ Calcium carbonate		
		$CaCl_2$ Calcium chloride	+	Na_2CO_3 Sodium carbonate	=	$2NaCl$ Sodium chloride	+	$CaCO_3$ Calcium carbonate		
$MgSO_4$ Magnesium sulphate	+	Na_2CO_3 Sodium carbonate	+	$Ca(OH)_2$ Calcium hydroxide	=	$Mg(OH)_2$ Magnesium hydroxide	+	$CaCO_3$ Calcium carbonate	+	Na_2SO_4 Sodium sulphate
$MgCl_2$ Magnesium chloride	+	Na_2CO_3 Sodium carbonate	+	$Ca(OH)_2$ Calcium hydroxide	=	$Mg(OH)_2$ Magnesium hydroxide	+	$CaCO_3$ Calcium carbonate	+	$2NaCl$ Sodium chloride

Note: Sodium hydroxide may be substituted for sodium carbonate and calcium hydroxide in the last two equations.

The amounts and kinds of coagulants added is regulated mainly by coagulation tests. Lime and sodium carbonate additions are regulated by chemical analysis and control tests. The control tests usually made are soap hardness and alkalinity.

After a complete analysis of raw water, theoretically required amounts of lime (calcium hydroxide) and soda (sodium carbonate) may be calculated from the reacting molecular weights of the compounds shown in above equations. See Table 5. Actually some excess of treating agent is desirable and due to impurities, an allowance of 5 to 10% should be made for lime and of 1 to 2% for sodium carbonate.

ZEOLITE TREATMENT.—The term "zeolite" is applied to such materials as have the property of base exchange. In water softening they exchange their sodium for calcium and magnesium in the raw water, these undesirable materials remaining with the

zeolite. Chemically, zeolites are hydrated silicates having a base such as sodium, a metal oxide as alumina, silica, and water of hydration. Their general composition is shown by the formula: $Na_2O \cdot Al_2O_3 \cdot (SiO_2)x \cdot (H_2O)n$. As used in water treatment zeolite is a hard granular material which may be of natural or synthetic origin. Synthetic material is more porous.

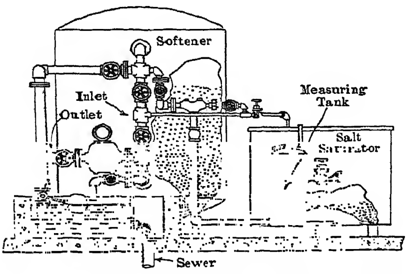

Fig. 3. Zeolite Water Softener (Wm. B. Scaife & Sons Co.)

A zeolite softener is similar to a pressure-type sand filter, except that a bed of zeolite replaces the fine sand. If raw water contains suspended matter, suitable filters should precede the zeolite softener, otherwise the zeolite may become coated. If water contain a large amount of temporary hardness, the zeolite treatment may be advantageously preceded by a cold lime coagulating and filtering treatment, resulting in less total solids in the treated feedwater. Hot water is destructive to zeolite, and temperature should not exceed 120° F.

Substituting Z for the zeolite radical, when water passes through a zeolite bed are

Sparingly Soluble Impurity	Treating Agent	Soluble Product		Insoluble Product
$CaSO_4$ Calcium sulphate	Na_2Z Sodium zeolite	Na_2SO_4 Sodium sulphate	+	CaZ Calcium zeolite
Calcium bicarbonate	Sodium zeolite	$2NaHCO_3$ Sodium bicarbonate	+	CaZ Calcium zeolite
$Mg(HCO_3)_2$ Magnesium bicarbonate	Na_2Z Sodium zeolite	$2NaHCO_3$ Sodium bicarbonate	+	MgZ Magnesium zeolite

Similar reactions occur with other calcium and magnesium compounds.

After a certain amount of raw water has passed through the zeolite the sodium must be replaced before the zeolite becomes completely exhausted and the hardness in the effluent water excessive. Regeneration is effected by washing the zeolite with strong salt solution for 30 to 40 minutes. The reactions are

Exhausted Zeolite	Treating Agent	Regenerated Zeolite	Soluble Waste Product
CaZ Calcium zeolite	$2NaCl$ Sodium chloride	Na_2Z Sodium zeolite	$CaCl_2$ Calcium chloride
MgZ Magnesium zeolite	$2NaCl$ Sodium chloride	Na_2Z Sodium zeolite	$MgCl_2$ Magnesium chloride

Calcium and magnesium chlorides from these reactions must be thoroughly washed out of the zeolite before resuming use of treated water.

When raw water contains large amounts of calcium and magnesium carbonates, a large amount of sodium carbonate alkalinity will be generated, which, in the absence of sufficient sodium sulphate, may promote caustic embrittlement. To avoid this, sufficient sulphate is added, either as sodium sulphate or by sulphuric acid treatment after the

Table 5.—Required Quantities of Reagents to Treat Calcium and Magnesium Compounds

One Part of	Requires Parts of	Produces Parts of	Parts of
$Ca(HCO_3)_2$.	0.457 $Ca(OH)_2$	1.235 $CaCO_3$	
$Ca(HCO_3)_2$.	0.494 NaOH	0.617 $CaCO_3$	0.654 Na_2CO_3
$CaCl_2$.	0.955 Na_2CO_3	0.901 $CaCO_3$	.053 NaCl
	0.779 Na_2CO_3	0.735 $CaCO_3$	.044
$Mg(HCO_3)_2$.	1.013 $Ca(OH)_2$	0.399 $Mg(OH)_2$	.368 $CaCO_3$
Mg(HC	1.093 NaOH	0.399 $Mg(OH)_2$	.449 Na_2CO_3
$MgSO_4$	0.881 Na_2CO_3	0.700 $MgCO_3$	.180 Na_2SO_4
$MgSO_4$	0.664 NaOH	0.484 $Mg(OH)_2$	.180 Na_2SO_4
$MgCl_2$	1.113 Na_2CO_3	0.885 $MgCO_3$	.227 NaCl
	0.840 NaOH	0.612 $Mg(OH)_2$	.227 NaCl

Note.—Lime and sodium hydroxide are the preferred reagents for treating the magnesiu compounds. A mixture of lime and sodium carbonate gives the same result.

zeolite treatment. The acid is added by automatic feeders, to insure against acidifying the feedwater. Phosphoric acid and acid phosphates have been added to reduce excess alkalinity and precipitate small amounts of calcium and magnesium passing the zeolite.

Natural treated zeolite material, usually known as greensand, weighs approximately 90 lb. per cu. ft. when dry. It has a rated exchange value of approximately 3000 grains per cu. ft. of hardness, as equivalent calcium carbonate. Synthetic zeolites weigh approximately 50 lb. per cu. ft. and have rated exchange values up to 9000 grains of hardness per cu. ft. The salt needed for regeneration varies with individual units, but for estimating, approximately 0.5 lb. of salt per 1000 grains of hardness may be used.

The zeolite treatment produces treated water with less hardness than any of the external chemical-treating methods. With a properly designed plant, hardness of treated water should not exceed 0.5 grain per gal. and should average less.

Evaporation of make-up water is especially useful in power plants where the percentage make-up is small and a minimum quantity of boiler deposit is desirable. This process produces purer water than any other process now available. The amount of make-up water which can be so prepared is limited only by economic considerations. See pp. 3–36 to 3–48 for a discussion of evaporators. Condensate from low-pressure boilers sometimes is used to supply make-up water for high-pressure boilers in which no appreciable quantity of scale can be tolerated. To assist continuous operation, feedwater to evaporators may be pretreated in the same manner as for boilers. In other cases it is preferred to crack scale from the evaporator tubes by the introduction of cold water when the scale is brittle. As with boilers, total solids in the water in the evaporator must be regulated to inhibit carrying undesirable quantities of solids into the steam.

Internal Boiler Water Treatment

Internal treatment consists mainly of maintaining desirable concentrations of chemicals in the boiler water. Chemicals to be added and concentrations to be maintained vary with the nature of feedwater and results of operation. The usual agents for inhibiting scale formation are sodium carbonate, sodium phosphate and sodium aluminate. Sodium hydroxide, tannates, and various prepared boiler compounds are used on occasion, or for some specific need. In general, prepared compounds are viewed with disfavor from both practical and economic standpoints.

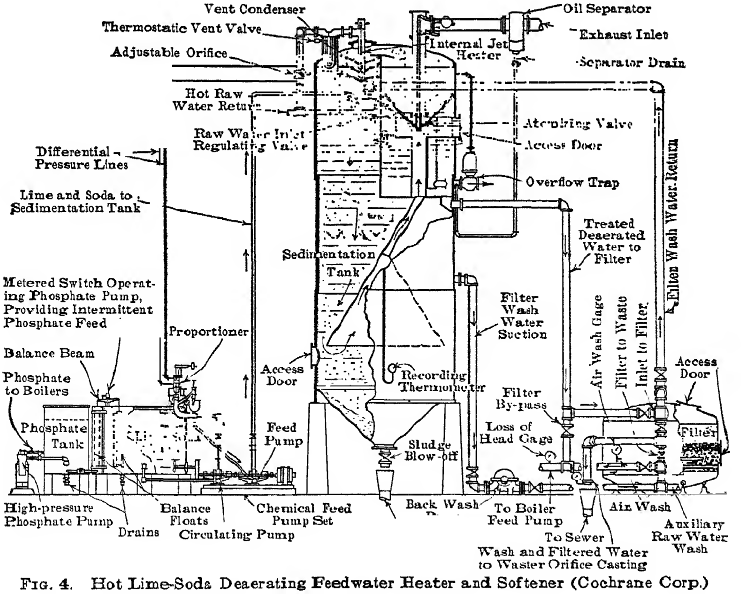

FIG. 4. Hot Lime-Soda Deaerating Feedwater Heater and Softener (Cochrane Corp.)

SODIUM CARBONATE is used to promote a desirable alkalinity and to inhibit formation of calcium sulphate scale. It also may retard formation of silica scale. In boilers, it hydrolyzes to form sodium hydroxide and CO_2 gas, the latter passing off with the steam. The extent of this reaction depends mainly on the amount of carbonate in the feedwater, but, in general, 70 to 90% of the sodium carbonate becomes sodium hydroxide.

Experiments indicate that under favorable conditions 2 to 3 grains of sodium carbonate in boiler water will inhibit calcium sulphate scale. The final concentration should be regulated by results of practical experience.

SODIUM PHOSPHATE is used principally to precipitate as tricalcium phosphate, calcium entering with the feedwater. This finely divided material has considerably less tendency to form objectionable deposits than the calcium compounds that otherwise would be present. A similar reaction may occur with magnesium, but in practice sufficient alkalinity usually is present to precipitate magnesium as magnesium hydroxide. The common forms of sodium phosphate are trisodium phosphate, Na_3PO_4; disodium phosphate, Na_2HPO_4; monosodium phosphate, NaH_2PO_4; sodium metaphosphate, $(NaPO_3)x$.

The less-alkaline phosphates, as monosodium phosphate, are used when there is excess alkalinity in feedwater or when calcium is present largely as calcium carbonate. Total alkalinity and total solids in boiler water thus are more easily controlled. Typical reactions of trisodium phosphate are

Soluble Impurity		Treating Agent	Insoluble Product		Soluble Product
$3CaCO_3$ Calcium carbonate	+	$2Na_3PO_4$ Trisodium phosphate	$Ca_3(PO_4)_2$ Calcium phosphate	+	$3Na_2CO_3$ Sodium carbonate
$3CaSO_4$ Calcium sulphate	+	$2Na_3PO_4$ Trisodium phosphate	$Ca_3(PO_4)_2$ Calcium phosphate	+	$3Na_2SO_4$ Sodium carbonate

Calcium phosphate thus formed has considerable tendency to adhere to feed lines. It generally is safer to add the phosphates direct to the boiler, or in intermittent doses, so that a minimum of precipitate is formed external to the boiler.

Provided there is sufficient alkalinity in the boiler water, the less-alkaline phosphates give the same type of reaction as above. The following is an example:

$3CaCO_3$	+	$2NaH_2PO_4$	+	$4NaOH$	=	$Ca_3(PO_4)_2$	+	$3Na_2CO_3$	+	$4H_2O$
Calcium carbonate		Monosodium phosphate		Sodium hydroxide		Calcium phosphate		Sodium carbonate		

Only a small amount of phosphate need be maintained in boiler water to inhibit scale. Phosphates, unlike sodium carbonate, do not lose efficiency by hydrolysis in boiler water. As with other forms of internal treatment it is important that boilers and other equipment in feedwater and steam systems be inspected and cleaned periodically.

SODIUM ALUMINATE usually is given the formula $Na_2Al_2O_4$, but in liquid form may contain a higher ratio of sodium to alumina. While generally recommended as a coagulant for external treatment, it also is used as a substitute or aid to sodium carbonate and sodium phosphate in internal treatments. It has many of the qualities of sodium carbonate. In addition it tends to make calcium and magnesium precipitates less adherent than if precipitated alone. Under certain conditions it will reduce silica concentration of boiler water, and form calcium or magnesium aluminum silicates, which are not generally adherent. However, under certain adverse conditions adherent silicates have formed, and the manufacturer of the material should be consulted.

For further information, see publications of National Aluminate Corp., Chicago.

Other Chemicals.—The use of other chemicals, as tannates and special boiler compounds usually is directed by vendors of the materials, or by consulting chemists.

3. EFFECTS OF IMPURE FEEDWATER

CORROSION.—Corrosion in boilers or feedwater equipment may be explained by the electro-chemical theory. See Eshbach, Handbook of Engineering Fundamentals, Section 11, forming Vol. 1 of this series.

The principal accelerators of corrosion in boilers are: 1. Dissolved oxygen. 2. Acids. 3. Surface deposits, especially those that are electro-negative to steel. 4. Unlike metal couples, as brass and steel. 5. Electrolytes, as strong salt solutions. Common methods of preventing corrosion are: *a*. Removal of dissolved gases in feedwater, especially dissolved oxygen and carbon dioxide. This can be done by deaerating processes. *b*. Neutralization of acids and maintenance of desirable alkalinity and hydrogen ion concentration (*p*H value) in feed and boiler water. See p. 6–68. *c*. Periodic mechanical cleaning

Protective paints may be applied if desired. *d.* Avoidance of excessive salt concentrations.

HIGH-TEMPERATURE CORROSION.—At higher temperatures, especially above 950° F., steam may react with iron according to the equation

$3Fe$	+	$4H_2O$	=	Fe_3O_4	+	$4H_2$
Iron		Steam		Black magnetic oxide		Hydrogen

At temperatures up to 950° F. this corrosion reaction is slow. Above this temperature the rate is accelerated, and alloys, like the Cr-Ni alloy KA2 are recommended. These materials form a protective oxide film on the metal surface, whereas steel does not. See J. K. Rummel, Corrosion by Superheated Steam (*Iron Age*, Dec. 5, 1929).

CORROSION FATIGUE.—Under certain conditions of corrosion and stress, metals may corrode in the form of deep sharp pits, which later develop into fissures or cracks. If the action is not stopped the parts attacked eventually will fail. The action may be produced by subjecting metal to ordinary corrosive conditions while under stress, which may be intermittent in nature. Microscopic examination shows the action to occur in a characteristic manner, producing cracks which are transcrystalline and in a nearly straight line. The products of corrosion fill the crack and the metal shows little or no elongation or distortion.

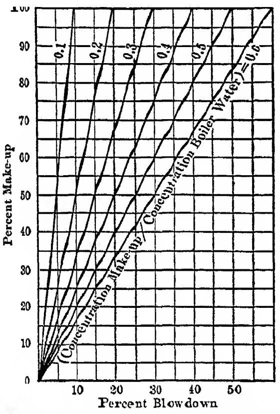

Fig. 5. Blow-down as Affected by Make-up and Ratios of Concentrations

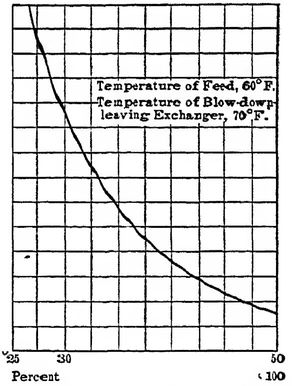

G. 6. Percentage of Blow-down that can be Used to Heat Feed to 210° F.

CAUSTIC EMBRITTLEMENT.—With certain types of feedwater, cracks of a peculiar form may appear in the boiler plates, particularly at the riveted seams below the water line. These cracks are intercrystalline and do not follow the lines of the maximum stress, as they sometimes run past each other and around parts or islands of the plate. This action has been termed caustic embrittlement, as it occurs where concentrated sodium hydroxide (caustic soda) is present in the water in the boiler in the absence of certain other elements.

Embrittlement is inhibited when a certain ratio of sodium sulphate to sodium carbonate is maintained in the feedwater. This has led to ratios, given in Table 6, of sodium sulphate to total sodium hydroxide and sodium carbonate alkalinity, calculated to equivalent sodium carbonate, being recommended for different working pressures in the Suggested Rules for Care of Power Boilers of the A.S.M.E. Code.

Embrittlement is caused by concentration of caustic soda at joints and through the effect of the stress in the metal at the joints. The trouble experienced with caustic embrittlement was a factor that led to the use of fusion-welded drums. See F. G. Straub, Embrittlement in Boilers, Univ. of Ill. Engg. Expt. Station Bull. No. 216.

Table 6.—Recommended Ratios of Sodium Sulphate to Total Sodium Hydroxide

Working pressure of boiler, lb. gage	0 to 150	150 to 250	250 and over
Sodium sulphate	1	2	3
Total sodium hydroxide and carbonate alkalinity as equivalent sodium carbonate	1	1	1

FOAMING AND PRIMING.—Foaming may be described as the formation of a large amount of foam in the boiler, due to failure of steam bubbles to coalesce and break. It is accompanied by considerable increase in moisture content of the steam.

Priming is characterized by large amounts of water passing out of the boiler with the steam, usually in intermittent slugs, which endanger steam lines, turbines, and engines. It may occur simultaneously with foaming. High water levels in boilers promote priming.

Foaming and priming generally are caused by high concentration of dissolved and suspended solids, possibly accompanied by oil and soaps in boiler water, and sudden changes in boiler capacity. These conditions may be prevented by reducing boiler water concentrations by blow-down, elimination of sources of feedwater contamination, periodic cleaning of boiler, and proper regulation of water levels. Since operating conditions and the boiler equipment influence the amount and kind of solids which may be permitted in boiler water, no general concentration limits can be given.

REDUCTION OF CONCENTRATION BY BLOW-DOWN.—Maintenance of reasonably low concentrations in high-capacity boilers is facilitated by economical continuous blow-down, with or without flash tanks, and with one or more heat exchangers. Fig. 5 indicates percentage blow-down required for any given percentage of make-up and ratio of concentration in make-up to that in boiler water. Fig. 6 indicates maximum percentage blow-down that may be utilized to heat feedwater from 60 to 210° F. for various steam pressures in the boiler.

Blow-down also may be used to heat part or all of the air for combustion. Fig. 7 shows the amount that can be so used for various steam pressures. The curves are based on air heated from 80° F. to a temperature 100° F. less than saturation temperature of the steam, with water leaving the heat exchanger at 190° F., assuming 1 lb. of air per 1 lb. of steam. For other air-steam ratios multiply percent blow-down by (lb. of air/lb. of steam). Tubular air heaters with extended surface on the air side and the continuous blow-down flowing inside the tubes are economical in cost, space, weight, and draft loss. With a small blow-down, part of the air, as primary air in pulverized coal firing, may be heated by the blow-down for mill drying. With a blow-down of 20 to 30% of the steam, all the combustion air may be heated in this way, using extraction feed heaters, and an economizer to secure desired boiler efficiency. The blow-down water leaving the air heater may be still further reduced in temperature in a feedwater heat exchanger before going to waste.

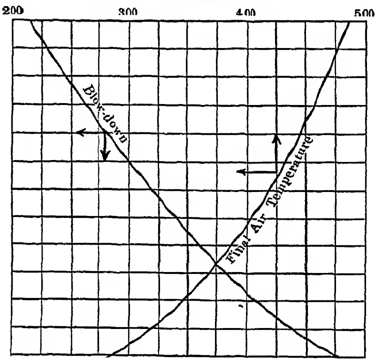

Fig. 7. Use of Blow-down for Heating Air

BOILER FURNACES *

By W. A. Carter

1. BURNING OF COAL

The complete combustion of coal in a furnace requires a sufficient supply of air, proper mixing of air and coal, adequate temperature to ignite the coal and maintain combustion, and sufficient time to complete the process. Hence, the furnace must provide a combustion chamber of sufficient volume and proper arrangement.

EXCESS AIR.—The amount of excess air beyond that theoretically required (see p. 4–07) depends on: 1. Composition and properties of the fuel. 2. General method of burning the combustible. 3. Manner in which air is supplied and mixed with fuel. 4. Arrangements and proportions used for grate and combustion chamber. 5. Furnace temperature desired, or that will be withstood by the furnace and related parts. Excess air will run from 25 to 50% for coal burned on grates or stokers. Half of the air, called primary air, controls rate of combustion; the remainder, or secondary air, controls completeness of combustion.

FURNACE TEMPERATURE LIMITATIONS.—Furnace temperature influences ignition of the fuel, rate of distillation of the volatile matter, proportion of CO formed, rate of combustion, and rates of heat absorption by various parts of the steam-generating unit. It is controlled by the amount of excess air supplied for combustion. If too high, furnace walls of refractory material will soften and deteriorate, and ash in the fuel bed may fuse into clinkers, which may adhere to walls and grates or stoker parts. This impairs operation and increases maintenance costs. Molten fly-ash carried in suspension in the gases may be deposited on refractory walls and cause slag erosion, or it may adhere to boiler tubes, thereby choking gas passages and limiting steaming rate.

COMBUSTION SPACE REQUIRED.—The size and arrangement of the combustion spaces should be such that flame will not be chilled and extinguished by contact with relatively cold surfaces before combustion is complete, and also such that all space will be used as fully as possible. Length of flame varies from a few inches with coke or anthracite, burning at low rates on grates or stokers, to 40 ft. or more with some volatile coals at high burning rates.

INFLUENCE OF CHARACTERISTICS OF COAL.—The physical characteristics of fuels may influence design or operation. Free-burning coals can be burned in a quiescent state; caking coals must be continually agitated while being burned, to permit passage of air. The ash of some coals fuses at temperatures of 2500° F. or higher and gives little trouble by clinkering; others have ash fusing at lower temperatures, causing much clinker trouble. Anthracite must be of uniform size to burn satisfactorily, while other coals burn best in run-of-mine or slack sizes. See U. S. Bureau of Mines Bull. 135, for quantitative information as to furnace volumes and lengths needed to burn three representative coals under various combustion conditions.

General Requirements of Combustion Equipment

SELECTION OF COMBUSTION EQUIPMENT.—The important factors to consider are: Grate area; draft for supplying primary air; provision for supply of secondary air; means for regulating and properly apportioning primary and secondary air; arrangement for mixing secondary air and volatile gases; means for maintaining combustion of the gases; combustion space of such volume as will provide for the length of flame; means for overcoming difficulties arising from coking of fuel or clinkering of ash; first cost of equipment; cost of labor, repairs, and maintenance.

Equipment should be selected with respect to: Character of fuel; ability to carry normal load at high efficiency and to meet maximum demand; ability to meet rapid changes in load; arrangement required for boiler, furnace, and other parts of the unit; ability to use preheated air, if desired; nuisance from smoke, cinder and fly-ash; loss from unburned fuel; loss from unit when fire is banked, and rapidity with which it can

* The author has drawn freely, by permission, on Heat Power Engineering by Barnard, Ellenwood and Hirshfeld (John Wiley & Sons) for many of the data in this chapter.

be brought from bank to full steaming capacity; durability of combustion apparatus and related equipment.

OPERATION.—To obtain maximum efficiency of combustion, the fuel bed should be uniform in thickness and character, and rate of feeding fuel should be constant. The evolution of gases should be unchanging in character and rapidity, sufficient primary air should be supplied to distill the volatile matter of the coal, with sufficient secondary air to complete the combustion process. Caked masses formed should be broken up constantly, and ash and clinker should be disposed of at a uniform rate.

2. HAND-FIRED GRATES

In hand-fired boilers, ideal uniform combustion cannot be maintained as firing is intermittent. The best condition of fuel bed is obtained when the coal is fired frequently, in small amounts, and with proper distribution; when caked masses of coal (if any) are broken up as rapidly as formed; and when ashes and clinker are not allowed to clog the fuel bed.

METHODS OF FIRING.—Three methods in general use for hand-firing boilers are:

Spread Firing.—A small amount of fresh coal is distributed evenly over the entire surface of the fire. It is commonly used with anthracite and other low-volatile coals.

Alternate Firing.—Fresh coal is fired on but one-half of the grate at a time. The freshly liberated volatile matter absorbs the necessary heat for combustion from the brighter parts of the fire. It is particularly suitable for non-caking coals.

Coking-Firing.—Especially suited to caking coals. Fresh coal is placed on the front edge of the fire and allowed to coke. After distillation is complete, the coke is spread over the fire. Lower rates of combustion are obtained with this method than with the other two.

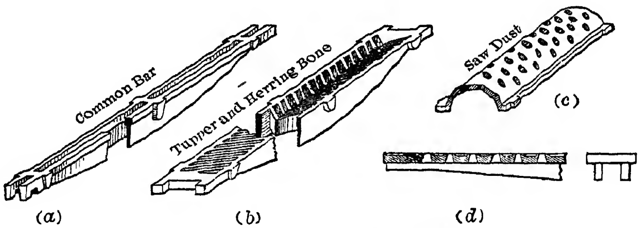

FIG. 1. Forms of Grate Bars

AIR APPORTIONMENT should be about equal between ash-pit door and openings in fire door. Draft should be adjusted by the boiler-outlet damper, either by hand or by an automatic damper regulator.

THICKNESS OF FUEL BED depends on furnace design; kind, size, and condition of coal; characteristics of ash; draft available, and steaming rate. In general, with natural draft, a thickness of from 4 to 8 in. is common with run-of-mine bituminous and anthracite buckwheat; with semi-bituminous coals, thickness is from 10 to 14 in. See U. S. Bureau of Mines Tech. Paper No. 80, Hand Firing Soft Coal under Power-plant Boilers; Univ. of Ill. Engg. Expt. Station Circular No. 7, Fuel Economy in Operation of Hand-fired Plants; Finding and Stopping Waste in Modern Boiler Rooms, Cochrane Corporation. Philadelphia.

COMBUSTION CHAMBERS in hand-fired boilers usually have firebrick walls. These, when hot, help to maintain the high temperature required for combustion. The combustion chamber often is of special form to compel the volatile gases to mix with secondary air.

With anthracite and other low-volatile coals a firebrick arch sometimes is sprung over the grate to assist ignition. The more volatile coals produce longer flames, and consequently the furnace must be made longer by setting it in front of the boiler as a Dutch-oven, or using a deflecting arch under the boiler to postpone contact of burning gases with the relatively cold boiler surface. The Dutch-oven furnace helps to attain smokeless combustion, except when the burning rate is high. Arrangements to mix air and volatile gases include multiple arches, piers or wing walls, and jets of air or steam injected through the front, sides, or bridge wall of the furnace.

COMBUSTION RATES depend on the characteristics of the coal and ash, thickness of fuel bed, total grate surface, air passage area of the grates, and the draft. Average rates, in lb. of fuel per sq. ft. of grate surface per hr. are:

Type of Draft	Anthracite	Semi-anthracite	Semi-bituminous	Bituminous Eastern	Bituminous Western	Lignite	Coke Breeze
Natural......	15	16	18	20	30	25	..
Forced.......	20	25	35	30	35	35	20

GRATE AREAS.—The old method of proportioning grate area, *i.e.*, $^1/_{30}$ to $^1/_{60}$ of boiler heating surface, may produce unsatisfactory results, and generally is inadvisable. The total width of grate surface usually is the distance between the walls of the setting; the length is made sufficient to provide the area necessary to burn the coal at reasonable combustion rates. For hand-fired anthracite, lengths up to 12 ft. have been used with dumping grates. For soft-coal the limit of length of ordinary grates usually is 6 ft.; if longer, it is difficult to clean fires. Table 1 gives the standard dimensions of grates for the setting shown in Fig. 9, p. 6-13.

Grate Bars should be so shaped as to present relatively small areas to the fire and expose large surfaces to be cooled by the currents of primary air. Fig. 1 shows several typical forms. The flat grate bar (*d*) for fine coal, is recessed on top to hold a layer of fine ash that protects the bar from heat and prevents adherence of clinker. Grate bars usually should not be over 3 ft. long. The width of air passage varies with the type and size of fuel as well as the type of draft, as shown in Table 2.

Shaking Grates are of many forms. The fire is more easily cleaned with shaking than with stationary grates, and it is not necessary to open furnace doors during cleaning. They cost more than ordinary grates, but with them from 1 to 5% better boiler and furnace efficiency is possible. Some forms of shaking grates also dump.

Inclined shaking grates, arranged to feed coal progressively from the front to a rear dump are known as hand-stokers.

3. STOKERS

The principal advantages of stokers over hand firing are: Continuous delivery of coal; progressive and gradual distillation of volatile matter; ability to obtain better performance and smokeless combustion because of the ease with which the operations can be regulated at all times; greater combustion capacity obtainable in a furnace; ability to meet varying load demands quickly; ability to burn poorer and cheaper grades of coal with less smoke and higher efficiency; relief of operators from strenuous duties, thus permitting more time for adjusting operating conditions; decreased labor costs in large boiler plants where the number of firemen can be reduced.

CLASSIFICATION.—Stokers are classified as overfeed or underfeed. Certain stokers of each type require forced draft; others operate with natural draft.

Overfeed Stokers include: 1. Front-feed, inclined-grate stokers; coal enters at the front, and is fed down an incline to the ash dump at the bottom; 2. Double-inclined,

84	20	6′-6″	7′-0″	45 1/2						

side-feed stokers; coal is fed from both sides, down inclined grates to a refuse pocket at the center. 3. Chain-grate or traveling-grate stokers; the entire coal bed moves horizontally from front to rear.

Underfeed Stokers include: 1. Single-retort stokers, usually horizontal, with lateral ash dumps. 2. Multiple-retort stokers, usually inclined with refuse discharge at the rear.

Table 3 shows types of stokers generally most suitable for the various fuels, as given by T. A. Marsh in Design and Application of Traveling-Grate Stokers (*Power*, Feb. 21, 1928). Table 3 should be considered as tentative, as the art of burning coal is still (1935) in the development stage. For example, the use of preheated air now permits fuels high in moisture to be burned by methods heretofore partly or wholly inapplicable.

Overfeed Stokers

Inclined overfeed stokers usually operate with natural draft. A coking arch at the front of the furnace, maintained at a high temperature, reflects heat to and distils volatile gases from the entering coal. Air, heated or otherwise, usually is admitted with coal under the arch. As a rule, these stokers require more attention than other types and seldom are used on boilers larger than 600 Hp.

Practically all kinds of coal, sawdust, tan bark, and hog fuel can be burned in these stokers, but they principally are used with high-volatile, high-ash mid-western coal. Average combustion rate with free-burning coals is from 15 to 25 lb. per sq. ft. of horizontal projected grate surface per hr., with a maximum of 35 lb. With caking coal, the maximum combustion rate is 25 lb.

INCLINED FRONT-FEED STOKERS include a hopper, coal-pusher feeding device, dead plate, coking arch, and inlet for secondary air under the arch. The action of the pushers and grate bars can be so regulated that when the coal arrives at the ash table, it has been completely burned.

DOUBLE-INCLINED SIDE-FEED STOKERS have coal magazines at each side of the furnace. These feed coal to a coking plate, where it meets heated secondary air brought through a refractory arch that covers the entire stoker. The grate bars are inclined, each alternate bar being in constant motion to feed coal down to the clinker

grinder. Exhaust steam from the stoker engine sometimes is admitted to the grinder to assist in breaking the refuse of clinkering coal.

Stokers of this type have large coking spaces, ample coking arches and large combustion chambers. Ordinarily they are satisfactory for both uniform and varying loads, but at high combustion rates and with certain types of coal, the fuel may avalanch.

Chain- and Traveling-Grate Stokers

CHAIN- AND TRAVELING-GRATE STOKERS comprise series of small links, forming a broad endless belt conveyor carried on rolls or skids. In the traveling-grate type, crossbars, extending from endless chains on either side of the furnace, support short interlocking grate bars. Both types are driven by sprockets at variable speeds, in conformity with the load on the boiler. Raw fuel is fed at one end and discharged as burned-out refuse at the other. The fuel bed is undisturbed while passing through the furnace. Natural or forced draft may be used, depending on the design. A minimum ash content of 7% is necessary to protect the back end of the stoker from heat. With a properly-designed furnace, this type of stoker can burn high-volatile coals without smoke, with either natural or forced draft, and also non-caking, clinkering coal, high in ash. Special designs can burn small-size anthracite and breeze, using forced draft. Modern (1935) designs are relatively free from siftings along the stoker sides, and from cold air past the sides, back end, and through the rear portion of the grate.

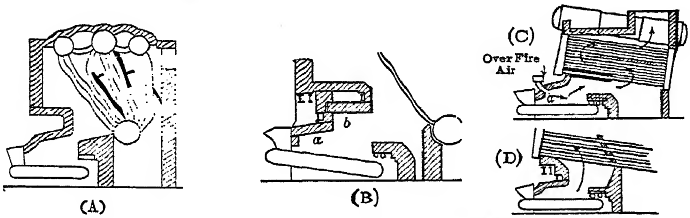

Fig. 2. Arch Arrangements with Natural Draft Chain-grate Stokers

Stokers of this type are relatively costly, but require little attention, and maintenance is low. They are not so well adapted as the underfeed stokers to meet sudden, heavy variations in demands for steam, unless forced draft is used.

Arches over the fire are necessary to cause mixing of gases from the rear of the grate, which are deficient in air, with excess air from the front. Another function is to maintain sufficient temperature to support combustion and to radiate heat to the front of the fuel bed to ignite entering fuel and distil volatile matter from it. Arches also prevent carrying away by a strong draft much of the fly fuel, which otherwise would be lost. Fig. 2 shows typical installations.

Secondary Air introduced under the front arch prolongs its life. A fan is preferable to a steam jet or induced draft.

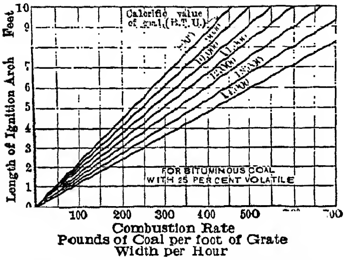
Combustion Space Requirements.—Adequate combustion chamber volume ordinarily should be provided by suitably locating boiler surface with respect to the grate according to recommended dimensions in Table 4.

Table 3.—Application of Stokers for Various Fuels

Fuel	Preferable Stoker
Anthracite	Traveling grate,* forced draft
Coke Breeze	Traveling grate,* forced draft
Semi-anthracite	Traveling grate,* forced draft
Semi-bituminous (coking)	Underfeed and inclined overfeed
Bituminous (coking)	Underfeed and inclined overfeed
Bituminous (free-burning, ash > 10 or 12%)	Traveling grate,* forced or natural draft
Bituminous (free-burning, ash < 10 or 12%)	Traveling grate,* underfeed or side inclined †
Sub-bituminous	Traveling grate,* forced or natural draft
Lignite	Traveling grate,* forced or natural draft

* "Traveling grate," is used to cover chain grates as well as traveling carrier-bar stokers.
† If ash fuses at a temperature below 2400° F., traveling grates are preferable. If the percentage of ash is less than 7, underfeed stokers are preferable.

Air Leakage around the grate may be minimized by: 1. Adjustable ledge plates to seal gaps between sides of stoker and furnace wall. 2. A tight ashpit to reduce infiltration at rear of stoker. 3. A well-fitted damper at the rear, between upper and lower runs. 4. A seal below lower run. A water-back, connected in the boiler circuit, set into an overhanging bridge wall, close to the grate, will compress the back of the fuel bed, and increase its density, thus decreasing air infiltration at this point. It also will reduce the amount of unburned fuel discharged to the ashpit, protect the bridge wall, and prevent adherence of clinker. Sidewall water-boxes may be necessary to prevent clinker building up on the furnace walls, which then may cause increased air leakage.



G. 3. Relation of Length of Arch and Combustion Rate

Operation.—The coal hopper outlet gate should be adjusted for proper thickness of fuel bed for the grade of coal burned, *i.e.*, 2 1/2 to 5 in. for fine anthracite, 4 to 6 in. for mid-west bituminous and lignite coals. The bed should be as thin as possible consistent with ignition and burning out at the proper point. Stoker speed and draft should be varied for load variations. For best results with the more volatile coals, coal that will pass through a 1 in. ring should be used, although screenings up to 2 in. will burn satisfactorily. A fuel bed of uniform density, offering correct resistance to air flow, is obtained with coal containing 50% fines. The addition of 3% moisture to the coal before firing will reduce sifting and blow-holes in the fire, and thereby reduce excess air and improve ignition. This extra moisture, reduces overall efficiency only a few tenths of 1%.

NATURAL-DRAFT CHAIN-GRATE STOKERS.—Free burning, high-volatile bituminous and sub-bituminous coals and lignite can be burned with high efficiency on natural-draft chain-grate stokers. The design of the arch depends on the percentage of volatile matter and heating value of the fuel, the combustion rate and the stoker length. With natural draft, an arch height of about 36 in. at the front has been found to give good results. Fig. 3 (T. A. Marsh, *Elec. World*, Oct. 23, 1920) shows the relation of arch length to ignition rate. The intersection of the ordinate corresponding to the product (combustion rate × stoker length) with the curve representing calorific value of fuel gives the length of the arch in feet. Fig. 2 shows several arrangements of furnaces for natural-draft chain-grate stokers. Turbulence of the gases is insured by the arches *a* and *b* in furnace *A*, and by increased velocity of gases in the narrow throats of the other furnaces.

Table 4.—Height of Settings for Various Types of Stoker-equipped Boilers *
(From Heat Power Engineering by Barnard, Ellenwood and Hirshfeld)

§ When burning coke breeze and anthracite fines, the setting heights indicated should be materially increased to provide for proper arch and furnace design.

Combustion Rates for most efficient operation with free-burning coal range from 20 to 30 lb. per sq. ft. of grate surface per hr., with a maximum rate of 40 lb. and a minimum of 5 lb. Draft loss, up to combustion rates of 35 lb., is approximately 0.1 in. of water per 10 lb. of coal per hr. per sq. ft. of grate, the loss increasing at higher combustion rates.

Operating Results possible with proper operation, without an economizer or preheater, are monthly efficiencies of boiler and furnace of over 70%, with CO_2 at the boiler outlet of 12 to 13%. Combustible in refuse should range from 15 to 25% at combustion rates of 25 to 40 lb. per sq. ft. per hr.

FORCED-DRAFT TRAVELING-GRATE STOKERS differ from natural-draft stokers in that a series of transverse independent forced-draft compartments, under the upper run of the traveling grate, are supplied, by a fan, with air under pressure from an air duct along the side of the boiler. Connections between the duct and compartments have dampers to control under-fire pressures in the various compartments. If the furnace has but a single arch, maximum under-fire pressure is carried only in the front compartment, the pressure tapering off to nearly zero in the rear compartment as shown in Fig. 4. In furnaces with front and rear arches, maximum under-fire pressure is at about two-thirds of the distance to the rear, pressures of $^1/_4$ to $^1/_2$ in. of water being carried in front and rear compartments.

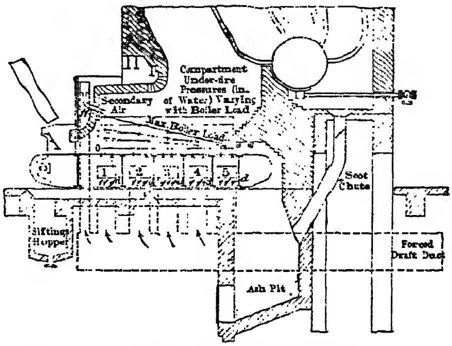

Fig. 4. Forced-draft Traveling-grate Stoker with Independent Air Compartments

Used with Low-volatile Coals.—For small-size anthracite, air openings in the grate must be small enough to prevent sifting. Special arrangements are necessary for primary kindling of the coal before it reaches the first forced-draft air compartment, utilizing heat radiated from the hot refractory surface of the arch. Entering fuel must "see" the arch through a greater angle, as *A* in Fig. 5 than that at *B*, through which it sees any relatively cold surface. In one stoker design, a small suction compartment at the front of the stoker draws some hot furnace gas down through the fresh fuel to ignite quickly moist or low-volatile fuels.

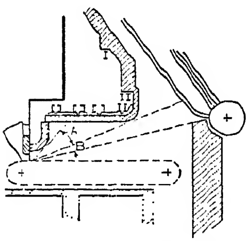

Fig. 5. Arch Arrangement with Traveling-grate Stoker for Anthracite

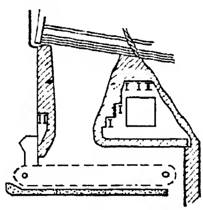

Fig. 6. Arch Arrangment to Reduce Stratification and Fly Ash

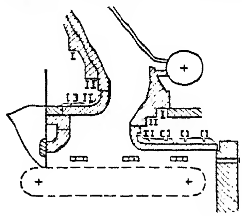

Fig. 7. Traveling-grate Stoker with Front and Rear Arches

Stratification of gases and carrying of fly ash by the furnace gases can be overcome by introducing air over the fire or placing the arch at the rear. See Fig. 6.

Front and rear arches often are used to form a narrow throat in which gases from the front and rear portions of the grate are mixed. Combustion is completed in the upper combustion chamber. See Fig. 7.

Used with Bituminous Coals and Lignite.—Forced draft under traveling-grate stokers permits higher combustion rates of free-burning coals than does natural draft. Efficiency curves are higher (5 to 6%). They also are flatter. Arches are smaller than with natural-draft stokers, but they must be set higher to prevent erosion. Side-wall water-boxes

and water-backs are necessary. Caking and coking coals that could not be burned on these stokers with natural draft are burned successfully with forced draft by reason of the air pressure breaking up the fuel bed. Water-cooled arches and side walls will avoid rapid destruction of brickwork by heat. An additional arch over the rear of the stoker is desirable when the coal varies in quality.

Combustion Rates for best results with bituminous coal should range from 30 to 40 lb. per sq. ft. per hr., with a maximum of 60 lb. when ash content ranges from 10 to 25%. A survey by N.E.L.A. in 1927 showed an average combustion rate of 43.5 lb. and average stoker maintenance cost of 4 cts. per ton of coal burned. With anthracite or coke breeze combustion rates range from 30 to 38 lb. per sq. f grate per h forced draft of 1.5 to 2 in. of water, with maximum and minimum rates of 55 and 10 lb. respectively.

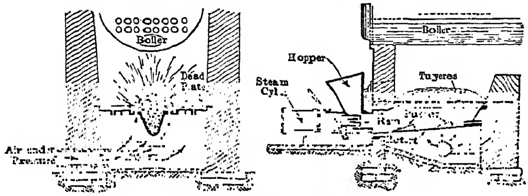

Fig. 8. Simple Horizontal Single-retort Stoker

Operating Results with bituminous coal should show combined boiler and furnace monthly efficiencies of 70 to 77%; CO_2 of 12 to 15%; combustible in refuse, 10 to 20%. With anthracite and coke breeze, monthly efficiencies of boiler and furnace should range from 72 to 76%.

Underfeed Stokers

Underfeed stokers operate at combustion rates as high as 110 lb. per sq. ft. of grate per hr. if ash fusion temperature is not below 2400° F. The field of the underfeed stoker comprises bituminous and semi-bituminous caking or free-burning coals, and to a lesser extent other grades of coal, including culm, coke breeze and small-size anthracite mixed with bituminous coal.

The essential principle of the underfeed stoker is a reciprocating ram or rams which feed coal from hoppers at the front of the furnace into the bottom of horizontal or slightly inclined retorts. The raw coal is underneath burning coal at the top of the fuel bed, which distils the volatile matter from the fresh coal. The liberated gases pass upwards through the burning coal, and are burned with air entering through tuyeres at the upper edges of the retorts. The coke which remains after distillation of the gases gradually is pushed upwards by entering fresh fuel and burns on the surface of the fuel bed. The entire fuel bed is worked toward the rear of the stoker or on to dead plates at the sides of the retort, ash and refuse being discharged into an ash hopper or removed by hand.

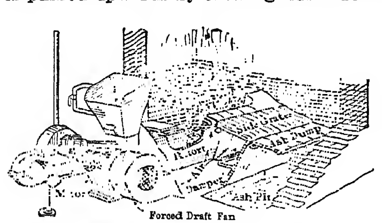

Fig. 9. Single-retort Stoker with Lateral Grates

Forced draft always is necessary. Rams and pushers, and sometimes also the ash disposal equipment, are driven by a motor or engine. Fuel and air supply can be regulated automatically by variations in steam pressure. Arches are unnecessary and considerable heat is transmitted to the boiler by radiation. This results in a relatively low temperature of gases passing through the boiler, even at high combustion rates.

SIMPLE SINGLE-RETORT STOKERS, Fig. 8, use a steam-driven ram or a screw feed, together with supplementary adjustable-stroke pushers, to properly distribute coal in the retort. From the surface of the fuel bed, refuse is deposited on dead plates whence it is removed by hand through doors in the front. In some designs the dead plates may be dropped to dump to the ashpit. Access doors on the sides of the furnace are unnecessary.

At moderate combustion rates, even with high-volatile coals, combustion is complete within a short distance of the surface of the fuel bed. The capacity of these stokers is from 800 to 1200 lb. of coal per hr. For greater capacities, two or three stokers may be set in a single furnace.

SINGLE-RETORT STOKERS WITH LATERAL GRATES resemble simple single retort stokers, except that stationary or movable overfeed grates are interposed between

the retort and the dead plates or dump plates. Air to the overfeed grates should be suitably regulated. The capacity of these stokers ranges from 1200 to 9000 lb. of coal per hr. The feed ram may be steam or hydraulically driven, or a motor-driven crank-shaft and connecting-rod may be used. This type of stoker may be used in boilers set side by side in continuous batteries, as no access doors in the sides of the furnace are necessary.

MULTIPLE-RETORT UNDERFEED STOKERS occupy the full width of the furnace. The fuel bed constantly moves from front to rear, and refuse is fed continuously to an ash dump. See Fig. 10. These stokers are from 6 to 28 ft. or more wide, with 3 to 16 retorts, and from 8 to 27 ft. or more long. Each retort may have from 13 to 69 or more replaceable tuyeres. Underfeed stokers can operate at higher combustion rates than other stokers, and in large units occupy a greater proportion of the area under the boiler. For a given rate of steam generation, they require less heat-absorbing surface, and permit individual units to have high steam generating capacity. These stokers can be brought quickly from bank to full capacity and can meet wide and rapid changes in load. Some furnaces have a stoker at each end discharging to a common ashpit.

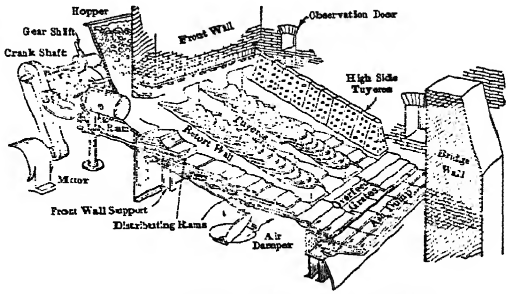

Fig. 10. Multiple-retort Underfeed Stoker

Control of the shape of the fuel bed to give proper air distribution is by adjustment of the length of pusher strokes and speeds of the various groups of rams. This also keeps the fuel bed open and free of clinkers. The active area of the fuel bed may be zoned, with independent regulation of air supply to each zone. A typical arrangement is shown in Fig. 11.

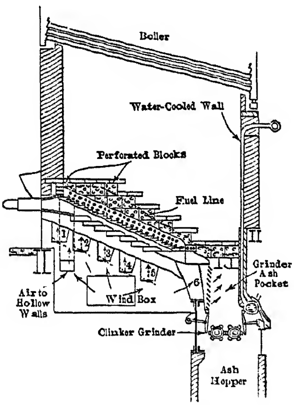

Fig. 11. Underfeed Stoker with Zoned Air Supply

Refuse discharging equipment comprises simple dump plates, double dumping grates, rocker plates and clinker grinders. With clinker grinders, the final combustible in the refuse can be reduced to 5% if the grinder pocket is large enough to hold ash for 12 hr., and air is forced through its walls. Shortening the time of burning out refuse to 6 hr. will raise the combustible to 15%. With dump grates, combustible in refuse may be from 15 to 25%.

Furnace walls for high combustion rates must withstand high furnace temperatures and erosive and slagging action of molten fly ash. Materials used are special grades of firebrick, silicon carbide blocks (if ash is not high in iron oxide), hollow perforated blocks through which secondary air is discharged, or water-cooled refractory or metallic blocks (see p. 6—95). The walls may be made hollow, and primary combustion air circulated through them. Protection from erosion and adhesion of molten clinkers may be obtained by the use of high air-cooled side-wall tuyeres (see Fig. 10) or water-cooled metallic surfaces (see Fig. 12).

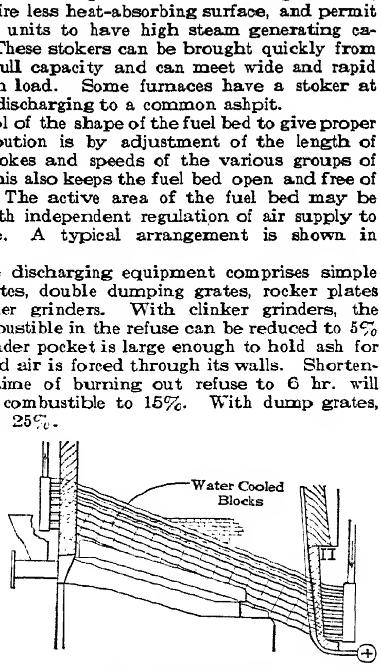

Fig. 12. Underfeed Stoker with Water-cooled Walls

Boilers fitted with underfeed stokers must be set in batteries of not more than two, as

access doors for inspection and cleaning of side walls are necessary in at least one side of the furnace.

Water-cooled underfeed stokers have been developed to burn low grade mid-western semi-bituminous coal, with ash fusion temperature as low as 1900° F., at a rate of 48 lb. per sq. ft. of grate surface per hr. (*Mech. Engg.*, Dec., 1935). Stoker tuyeres are cooled by forced circulation of water through groups of three tubes laid lengthwise of each tuyere stack, extending downward over stationary extension grates to a header near the clinker grinders. Groups of shorter tubes protect the remainder of the extension grates that register with the lower ends of the retorts. Side and rear furnace walls of such installations should be water-cooled to withstand the action of ash with such low fusion temperature.

Combustion Rates may range from bank to 75 lb. of coal per sq. ft. of projected grate surface per hr. The upper limit depends on kind of coal, furnace design, and available draft. With zoned-air control, combustion rates as high as 110 lb. have been carried. Without zoned-air control, best operation is at combustion rates of 35 to 45 lb., although rates as high as 90 lb. have been carried satisfactorily. The usual average in central stations, according to an extensive N.E.L.A. survey in 1928, was 50 lb.; average total stoker maintenance cost was 9.5 cts. per ton of coal burned.

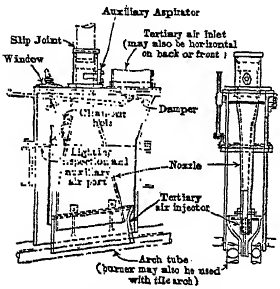

FIG. 13. Streamline Fan-tail Burner

Operating Conditions.—Excess air required with underfeed stokers is relatively low, but it should not be reduced to a point where boiler exit gases contain CO, or furnace temperatures are greater than furnace walls can withstand. Forced-draft pressures range from $^3/_4$ to 1 in. of water per 10 lb. of coal burned per sq. ft. of projected grate surface per hr. Air preheated to 300 to 500° F. sometimes is used. The closure of stoker air passages by expansion and growth of metals must be avoided by proper design and material. Prohibitive stresses and distortion also must be avoided.

Power required to operate such stokers may be, under extreme conditions, as much as $^3/_4$ to 1 Hp. per retort, burning from 700 to 1100 lb. of coal per hr.

Gross Efficiency of large steam-generating units with economizers, but without air preheaters, and equipped with multiple-retort stokers ranges from 90% at low loads to 75% at high loads. Under such conditions, excess air will vary from 20 to 10%.

Manufacturers of representative stokers are: *Overfeed Stokers:* Detroit Stoker Co., Detroit; Riley Stoker Corp., Worcester, Mass. *Chain- and Traveling-grate Stokers:* Babcock and Wilcox Co., New York; Combustion Engineering Co., New York; Laclede Stoker Co., St. Louis; Riley Stoker Co., Worcester, Mass. *Underfeed Stokers:* American Engg. Co., Philadelphia; Combustion Engg. Co., New York; Detroit Stoker Co., Detroit; Hoffman Combustion Engg. Co., Detroit; Riley Stoker Corp., Worcester, Mass.; Westinghouse Elec. and Mfg. Co., East Pittsburgh, Pa.; Whiting Corp., Harvey, Ill.

4. PULVERIZED COAL*

To insure complete combustion, the coarser coal particles must have motion relative to the gases surrounding them, which removes products of combustion and volatile matter, and supplies additional oxygen. This is accomplished by intensive mixing of the pulverized coal, resulting in turbulence. When secondary air is used, it is injected, at velocities of 60 to 150 ft. per sec., crosswise into the coal-carrying primary air. Turbulence reduces flame length, increases the effectiveness of the furnace and permits a smaller furnace to be used for a given output. Flame length varies with size of the fuel particles, being shortened by finer and more uniform pulverization; other factors are percentage and composition of volatile constituent, furnace temperature, and excess air. Turbulence may reduce flame length to less than 10 ft. Long flames can be given helical or U-shaped paths, the shape of the furnace being adapted to the space available.

BURNERS.—The essentials of a good burner are uniform turbulent mixture of coal and primary air, with provision so to regulate the flow of both coal and air as to give good combustion at minimum, normal and maximum loads. It should not produce flames of excessive length or velocity, nor offer excessive resistance to air and coal flow. The metal exposed to radiation should be a minimum, and the burner should be capable of easy cleaning. Furnace volume may be decreased by improving combustion conditions in the burner.

* See also pp. 4–28 to 4–37.

Factors influencing burner design and operation are the fineness, surface moisture, and volatile matter of the coal, and the size and porosity of the coke particles formed, the quantity, temperature and pressure of primary and secondary air, and the method of mixing air and coal. Furnace design and load variations also are important factors. The usual range of burner capacity is from 2 to 3 $^{1}/_{2}$ to 1; if a wider range in boiler capacity is needed, it is obtained by changing the number of burners in operation. Burners are of either stream-line or turbulent type.

To prevent flare-backs, the velocity of fuel and primary air through the piping and burner always must be greater than that of flame propagation. The tendency of turbulence is to equalize conditions across the coal-air stream, and both shorten and widen the flame. It is easier to produce initial turbulence than to maintain it further along in the furnace.

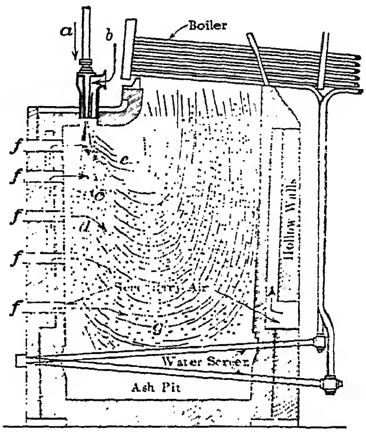

Fig. 14. Action of Stream-line Burner
a, Coal and 10 per cent air; *b*, 20 per cent air; *c*, velocity 100 to 150 ft. per sec.; *d*, velocity 10 to 15 ft. per sec.; *e*, fine coal particles; *f*, about 65 per cent air; *g*, coarse coal particles

Primary Air Ratio.—The ratio of primary air to coal should be kept as nearly constant as possible. In unit systems it varies widely with load, and adjustments are made at the burner outlet to obtain proper velocity of mixture entering the furnace. With the bin system, the primary-air-coal ratio is under control at all times. With a single burner, the ratio is set for moderate fuel-burning rates, and a lower ratio is maintained for higher loads than for lighter ones. With a multiple-burner bin-system installation, the ratio can be held constant, and the fuel burning rate varied by the number of burners in operation.

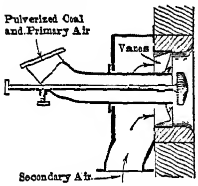

Fig. 15. Turbulent Circular Burner

With refractory furnace walls, it sometimes is necessary to increase the air-fuel ratio at higher loads in order to limit furnace temperature. The primary air fed with the coal varies with the type of burner, from a small percentage to 100% of the total air.

Stream-line Burners produce long flames with little or no turbulence. Fig. 13 shows a simple form of stream-line fan-tail burner, used in vertical firing. It discharges thin, flat streams of primary air and coal downward, as shown in Fig. 14. The streams are parallel and edgewise to the front furnace wall. Secondary air passes through the hollow refractory wall, thereby cooling it, and enters the furnace through ports in the front wall at sufficient velocity to produce turbulence when it meets the air-coal stream from the burner. The nozzles of these burners sometimes are ribbed, serrated, or rifled; deflectors at the outlet may cause jets of tertiary air to strike the primary stream. Such expedients tend to shorten the flame.

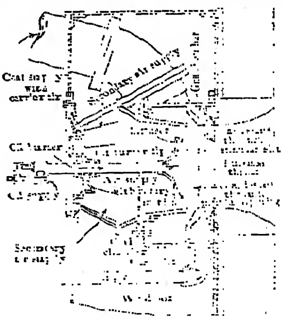

Fig. 16. Combination Burner for Coal, Oil or Gas

Turbulent Burners may have circular or straight narrow outlets. Secondary air passes through them, under either forced or induced draft, and meets the coal-laden primary air as the two enter the furnace. In comparison with a stream-line burner, the flame is short and flaring. Fig. 15 shows a simple form of circular burner, which usually discharges horizontally through refractory walls. Primary air and coal flow through the central nozzle, at the end of which is a diffuser. Secondary air flows under pressure through the annular chamber surrounding the coal stream, and which frequently contains adjustable guide vanes. Provision is made to regulate the flow of both coal and air. Fig. 16 shows a combination burner that can burn pulverized coal, gas, or oil, or all in combination.

Fig. 17 shows a turbulent intertube burner installation between the vertical tubes of water-cooled furnace walls. Secondary air jets entering under pressure through oblique ports, arranged alternately on either side of each stream, break up the vertical streams of primary air and coal. These burners are suitable for furnaces with bottoms designed for coals whose ash has high fusion temperatures.

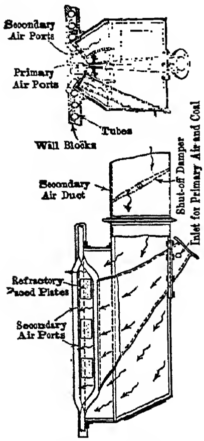

Fig. 17. Turbulent Intertube Burner

The cross-tube burner, Fig. 18, was developed for furnaces with slag-tap bottoms, in which low-fusion temperature ash must be held molten. The burner discharges primary air and coal through a horizontal slot into spaces between the vertical water-wall tubes, either horizontally or at an angle. Secondary air enters through adjustable tuyeres in the furnace wall, above and below the coal stream, and distributes the flame

FEEDERS to regulate delivery of pulverized coal into the primary air stream are required with the bin system; with the unit system feeders are unnecessary as primary air is fed through the unit pulverizer and picks up the coal when it is suitably pulverized. Feeders must be designed to prevent flooding, because of the fluid character of dry pulverized coal.

Feeders use revolving screw conveyors, belt or chain conveyors, revolving plates, star wheels, rocking gates, revolving pockets, or reciprocating pushers. Conveyor types utilize a spring-loaded regulator to prevent flooding. In one screw-conveyor type, primary air, as it passes the end of the screw under pressure of 8 to 20 in. of water, entrains the coal and carries it to the burner. Dampers control the primary air.

Feeders usually are attached to the bottom of pulverized coal bunkers with louvre gates between, and have agitators to pre- coal from packing or bridging.

FURNACE DESIGN The burning of coal in pulverized form imposes certain requirements in the design of boiler furnaces chiefly in respect to the fusion temperature of the ash and the type of furnace walls. Larger furnace volume for a given heat release rate is required than with other fuels. The report of the International Railway Fuel Assoc. (*Power*, June 19, 1928) shows heat release rates ranging

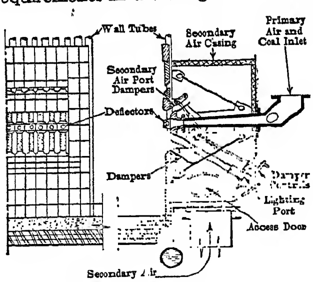

Fig. 18. Cross Tube Burner

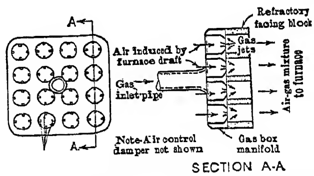

Fig. 19. Gas Burner Giving Moderate Mixing

from 15,000 B.t.u. per cu. ft. of furnace per hr. with solid refractory walls to 30,000 B.t.u. with water walls, with ash fusion temperature above 2400° F.; and from 12,500 to 22,000 B.t.u. with ash fusion temperatures of 2100–2400 B.t.u. See also p. 6–89.

Manufacturers of representative burners and feeders are: Babcock & Wilcox Co., New York; Combustion Engg. Co., New York; Riley Stoker Corp., Worcester, Mass.

5. GAS BURNERS

Gas burners used in boiler furnaces differ in the degree of mixing fuel and air that occurs in the burner. Long, luminous flames result from burners in which mixing is slight; short, non-luminous flames come from burners that mix gas with all of the combustion air.

Aspirating burners generally are used in boiler furnaces. Fig. 19 shows a type that produces a moderate amount of mixing. Gas is introduced in various ways. In Fig. 16, which shows a combination burner for gas, pulverized coal, and oil, a film of gas flowing

around the circumference of the burner throat replaces the numerous small jets of Fig. 19. Either natural or forced draft may be used.

The Venturi-type burner, with a central nozzle for gas injection is used for rapid mixing. Primary air is induced by the reduced pressure in the Venturi throat. See Fig. 20. A modified Venturi-type burner, in which mixing is done in two stages, is shown in Fig. 21.

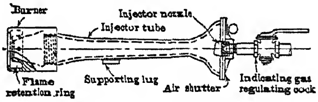

FIG. 20. Venturi-type Gas Burner

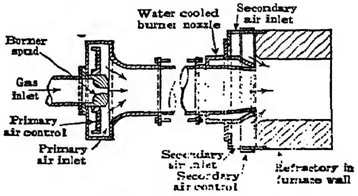

FIG. 21. Modified Venturi-type Gas Burner

FURNACE REQUIREMENTS.—Special requirements are imposed on the design of boiler furnaces by the burning of gas. See p. 6–11.

Manufacturers of representative gas burners are: Bethlehem Steel Co., Bethlehem, Pa.; Hauck Mfg. Co., Brooklyn, N. Y.; Peabody Engg. Corp., New York; Todd Combustion Equipment, Inc., New York.

6. OIL BURNERS *

The principal requisites of an oil burner are: It must completely atomize or vaporize oil; it must not clog or drool; the jet must be so shaped that it will completely mix with the air necessary for combustion; combustion must be complete and excess air at a minimum over the entire operating range; the burner must be accessible for cleaning, and require a minimum of attention.

Vaporizing burners are not used in large boiler furnaces. Two classes of atomizing burners are used: 1. Those that effect atomization by spraying, usually by steam jets, although jets of compressed air may be used. 2. Those that atomize mechanically, without any atomizing fluid.

STEAM-ATOMIZING BURNERS use the atomizing fluid to break the oil into minute particles and carry them into the furnace. These burners are either outside-mixing or inside-mixing. Steam for atomization should be at a pressure of 25 to 80 lb. per sq. in., gage. The amount of steam required for atomizing, pumping and heating the oil depends on the burner design and the method of control, ranging from 2 to 7% of the total steam generated. The temperature of the oil delivered to the burner at a pressure of 40 to 60 lb. per sq. in., gage, is 150° to 190° F. This type of burner seldom is designed to pass more than 1000 lb. of oil per hr. when using natural draft, but at least one design can burn 1500 lb. when using air at a pressure of 2 in. of water in the air register around the burner.

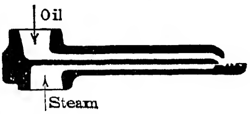

FIG. 22. Outside-mixing Burner

FIG. 23. Inside-mixing Burner

Outside-mixing Burners usually are confined to boilers operating at moderate rates, with little change in load. Fig. 22 shows a simple form giving a flat flame. Combustion air enters through checker work forming part of the furnace hearth. The combination of flame shape and method of supplying air limits the furnace to a single row of burners. Forcing the burner causes incomplete atomization, resulting in slower burning, smoking fouling of boiler surfaces, and decreased efficiency.

Inside-mixing Burners may be built to give either flat or hollow conical flames. Fig. 23 shows one of the former. In the latter the flame is short, and air readily enters it. Air is induced, through controllable registers enclosing the burner, by the furnace

* See also p. 4–49.

draft and by aspiration of the steam jet. Air pressure, at high combustion rates, is up to 2 in. of water. These burners can be set in multiple rows, providing any reasonable range of boiler operation, limited only by furnace volume.

Under certain operating conditions, steam atomizing burners may be noisy. The blow-pipe action may injure the walls of improperly constructed furnaces. Other objections are additional moisture produced in flue gases and the cost of steam for atomizing. Nevertheless, they are widely used in small plants because of their low initial cost and freedom from complication.

MECHANICAL-ATOMIZING BURNERS comprise rotary burners and spray-nozzle burners. The former is used only under low-pressure boilers.

Spray-nozzle Burners are practically the only ones used in power-plant boiler furnaces. Oil under a pressure of 50 to 300 lb. per sq. in., and at temperatures of from 100° to 350° F. issues in a hollow cone from a small orifice in the nozzle. Suitable passages in the nozzle cause a whirling motion of the oil as it is liberated. Combustion air enters, under furnace or forced draft, through a register around the burner; in some cases it is given relative motion with respect to the flame. Fig. 16 shows a typical combination burner for oil, gas and pulverized fuel.

The steam equivalent of the power required to spray the oil seldom is more than 1% of the total steam generated. Oil-burning capacity ranges from 2000 to 2500 lb. per hr. with combustion air pressures up to 6 in. of water. Several rows of burners can be installed in a furnace wall to obtain higher capacities.

Earlier methods of regulating the weight of oil delivered by spray-nozzle burners were not entirely satisfactory. Variation of oil pressure does not permit a large range of regulation, as proper atomization is not obtained with pressures below 50 lb. per sq. in. Regulation by changing burner tips is objectionable as it interrupts operation. Regulation by varying the number of burners in operation is undesirable, as it causes poor air distribution.

A more satisfactory method of regulation is to by-pass a regulated quantity of oil from the burner to supply tank or burner header. Another method provides two independent sets of oil feeds to the burner tips, using either or both in accordance with the demand for steam. These methods permit of variation of the oil burning rate, from the maximum to a minimum rate of 15 to 35% of maximum, with slight change in the spray.

Manufacturers.—A list of manufacturers of representative oil burners is given on p. 4–52.

7. BOILER FURNACE DETAILS

General

FACTORS INFLUENCING FURNACE DESIGN.—Fuel and character of load are the most important items to consider in furnace design. The kind and characteristics of the fuel, including the properties of its ash, determine the method of burning it. For instance, solid fuels may be burned on grates, on stokers or in pulverized form; the method of firing and type of burner are factors. Other items that will need to be considered in connection with the fuel are the amount of excess air, which influences boiler capacity and efficiency, and allowable carbon in fly-ash and in refuse. The load characteristics include the minimum, normal and maximum loads, and the duration of each. Heat release rates also are important, in that an increase in rate will tend to decrease the size of the boiler for a given output of steam. This, in turn, affects the material and construction of furnace walls. Maximum temperatures for a given type of wall construction also must be determined. The number of variables involved require, for the most economical arrangement and construction, that each furnace be considered as a special case.

TYPES OF FURNACE WALLS, in the decreasing order of furnace volume per unit of steam output, and in the increasing order of heat release rates and furnace temperatures, are: Solid refractory walls; hollow air-cooled refractory walls; bare water-cooled metallic walls, covered water-cooled metallic walls. The water-cooled walls are necessary for long-continued operation at high combustion rates and high temperatures. Solid refractory walls are suitable and economical for moderate rates and temperatures. For intermediate conditions, the hollow air-cooled wall or a combination of refractory and water-cooled walls may be satisfactory. Superheater or reheater surface may be substituted for some refractory or water-cooled surfaces.

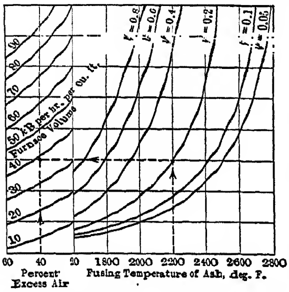
Increasing excess air, to reduce furnace temperatures and decrease wall failures, is inadvisable in ordinary operation, as it also reduces efficiency; it may be justified at peak loads. The use of preheated air usually causes higher furnace temperatures than

the use of room air. For long-continued, high-temperature operation, furnace walls should be designed with these conditions in mind.

MAXIMUM ALLOWABLE FURNACE TEMPERATURE depends on the behavior of the particular combination of fuel, ash, and material in the hot faces of the furnace walls. Depending on the composition of the ash, its fusion temperature, and the furnace-wall temperature, a refractory wall may be affected by slag penetration, chemical reaction, or erosion by molten slag running down the wall. If the temperature of a coal-fired furnace is not quite high enough to cause any of these effects on a solid refractory wall, solidified fly ash may deposit on it until the combined thickness will become so great that the temperature at the surface equals the ash fusion temperature. Variation in furnace temperature will cause the fly-ash to melt or build up until equilibrium is established. The same is true of air-cooled or water-cooled refractory walls. Metallic walls give the least difficulty from adhering fuel ash, although fused ash flowing over them will, in time, be destructive.

Furnace Volume

Furnace volume depends on the total amount of heat required in a given time and on the permissible B.t.u. release per hr. per cu. ft. of furnace volume. This heat-release rate depends on type of furnace construction, flame length, ash fusion temperature, method of firing, amount of excess air and amount of turbulence in furnace. Table 5 gives permissible heat-release rates.



ψ = fractions cold. kB = 1000 B.t.u.

FIG. 24. Relations Existing in Furnace

Since the heat-release rate in hand-fired furnaces is limited, the grate in horizontal return tubular boilers can be set within 3 or 4 ft. of the boiler surface, and within 4 to 4 1/2 ft. in horizontal water-tube boilers fired with volatile coal. With anthracite the distance can be slightly less. With stoker-fired furnaces, the distance should be made greater. See Table 3. For very high rates of combustion, even greater distances are required.

Pulverized-coal Furnace Volume usually is larger or the heat-release rates lower, than in furnaces of equal capacity burning any other fuel. In general, under identical conditions, higher heat-release rates are [illegible] all units than in large, since the rati[o] of wall surface to volume is greater. Fig. 24 (Some Factors in Furnace Design for High Capacity, E. G. Bailey, *Trans.* A.S.M.E., FSP–50–78, 1928) shows approximate relations between heat-release rates, amounts of excess air, fusing temperatures of ash, and fractions cold (ψ).

$$\psi = \frac{\text{(actual extent of cold surface in furnace)}}{\text{(maximum possible extent of cold surface in furnace)}}$$

Furnace design should consider the conditions to be met by the various elements of volume and wall surface. The use in design of average heat-release rates and average temperatures (which have been used in the above discussion) may lead to trouble because localized temperatures may be much higher than average temperatures.

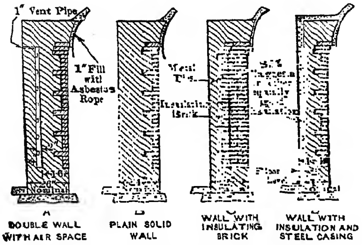
Solid Refractory Walls

Solid refractory walls are usual in the furnaces of externally fired boilers, with low heat release rates. The walls usually are integral with the boiler setting, and are built of high-grade firebrick, second grade firebrick, insulation, or some combination thereof. Some typical furnaces are shown below.

Table 5.—Average Heat-Release Rates

Method of Firing	Solid Refractory Walls		Water-cooled Metallic Walls	
	Continuous Operation	Peak Operation	Continuous Operation	Peak Operation
	B.t.u. per hr. per cu. ft. of furnace volume			
Chain- or traveling-grate stoker....	15,000	25,000	30,000	45,000
Underfeed stoker................	25,000	40,000	30,000	45,000
Pulverized coal firing.............	15,000	20,000	25,000	35,000
Oil firing........................	20,000	40,000	30,000	60,000
Gas firing.......................	20,000	40,000	30,000	60,000

HORIZONTAL RETURN TUBULAR BOILERS.—The conventional setting is shown on p. 6–13. Fig. 25 and Table 6 (Boiler Book of Hartford Steam Boiler Inspection and Insurance Co.) show approved constructions. Type B is the least costly but is more liable to air leaks than Type A. The hollow space in Type A should be filled with sand or ashes to retard air infiltration in the event of cracks in the inner wall. Type C is more costly than type B. The insulation reduces heat loss through the walls, and raises the furnace temperature. Higher grade lining, therefore, is necessary. Metal ties are advisable to bond the lining to the outer walls, as the insulating brick have little mechanical strength. Type D is the most costly setting. It is similar to Type B, excepting that 85% magnesia replaces the hollow space, and a steel casing of No. 8 gage steel plate encloses the entire setting. Heat radiation is a minimum and air infiltration is completely inhibited. The sections shown apply to the side walls at the rear of the bridge wall. In the furnace section a batter out of 6 in., from the grate level to the closing-in line near the middle of the boiler shell is recommended. Allowance for expansion should be made between the bridge wall and side walls. Relieving arches sometimes are built into the tops of furnace side walls, to permit of easy replacement of furnace walls without shoring up of the upper parts of the walls. Ample foundations are necessary to prevent settling and cracking of walls. Vertical buck stays and cross-tie rods are essential to prevent bulging of side walls. It usually is desirable to protect the blow-off pipe from flame impingement by a brick baffle. See Fig. 9, p. 6–13.



Sections apply to side walls at rear of bridge wall

FIG. 25. Typical Horizontal Return Tubular Furnace Settings

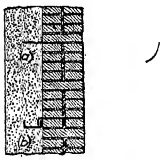


FIG. 26. Monolithic Wall Lining

Jointless Monolithic Wall Linings are made of plastic fireclay rammed into position, and tied to the outer walls: three methods are shown in Fig. 26. Space should be allowed for expansion at the abutting ends of the lining; it is desirable to fill this space with loosely-packed mineral wool, to prevent it filling with slag. Plastic fireclay also may be used to patch or reline old walls, if the old brickwork first is chipped free of slag and the openings to be filled are undercut to provide a lock for the new material. Refractory cements, best applied with a spray gun, often are used to resurface old walls.

Outer surfaces of brick settings are made impervious to air-infiltration by applying special sealing materials that remain semi-plastic even on the hot surfaces. Although such materials improve efficiency of combustion in furnaces with leaky walls, they also cause hotter furnace linings by eliminating air leakage, which has a cooling effect on the brickwork.

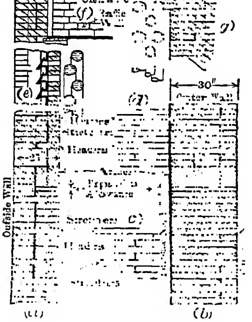

FIG. 27. Wall Construction for Horizontal Water-tube Boilers

WATER-TUBE BOILERS.—Stoker-fired furnaces may have solid refractory walls, whose arrangement depends on the type of stoker and boiler. The boiler should be so suspended from overhead beams that it cannot at any time come in contact with the furnace walls. Bridge walls and furnace linings should be high-grade firebrick. Cheaper grades of brick can be used behind the lining. Relieving arches, amply buttressed to carry thrust, may be built into the walls to relieve the load on the lower brick, in high settings, or to assist in wall repairs; expansion space should be provided below them. The upper part of high furnace walls sometimes is anchored to external steel work to prevent the wall falling inward as a result of alternate heating and cooling.

The common wall of furnaces grouped in batteries of two should be entirely of high-grade firebrick and much thicker than the side walls. Fig. 27 gives

Table 6.—Dimensions and Material Quantities of Horizontal Return Tubular Boiler Settings. (See Fig. 25)

* For one boiler; for two boilers double the number required for one boiler.

typical sections through one type of wall construction for horizontal water-tube boilers. To avoid overheating, steel work supporting the boiler should not be enclosed in the brickwork.

In tall settings, walls often are built concave toward the fire, and the upper parts are so built that when cold they lean outward as much as 5 deg. from the vertical. This prevents their bulging or leaning inward when heated.

Clinker Belts, *i.e.*, the lower parts of side walls of the furnace, adjacent to and just above the fuel bed, usually require special construction, as they are subject both to intense heat and to adhesion of clinker if the wall is of ordinary firebrick. Clinker not only cuts down effective grate surface, but allows excessive air to flow through as a result of their scraping the sides of the moving fuel bed. Removal of clinker from a solid refractory wall by a slice-bar destroys the wall. Several solutions are available to meet these severe conditions. The wall at this point may be built of special slag-resisting blocks which may be solid, or hollow (see Fig. 11), or air- or water-cooled metallic wall sections may be used. (See Figs. 10 and 12.)

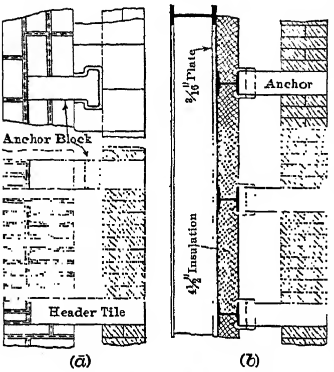

FIG. 28. Self-supporting Air-cooled Refractory Wall

Joints in Refractory Walls are vulnerable points for slag attack. The brick should be laid with a fireclay mortar with refractory properties equal to those of the brick itself. Finely-ground raw fireclay and as much finely-ground calcined fireclay or ground firebrick, free from slag, as will stay in suspension in a batter should be used in laying the brick. Such material serves as a filler and is adequate; bonding mortar seldom is required. Joints should be as thin as possible. If accurately sized brick are not available, each course of brick should be rubbed level with a silicon-carbide block before laying the next course. A thin coat of filler, of the consistency of batter, should be poured over the leveled course, and each brick, after being dipped in the batter, should be slid and tapped into place.

Backing-up brick is bonded to the inner lining by header and stretcher courses. If the lining is only 4 1/2 in. thick, every fourth or fifth course should be a stretcher course as *d* in Fig. 27. A 9-in. wall can be laid as header courses with every fourth or fifth course a stringer course, *i.e.*, a header course behind a stretcher course (*a*, Fig. 27).

Air-cooled Refractory Walls and Arches

Air-cooled refractory walls are either entirely self-supporting, or sectionally self-supporting. Cooling air flows through ducts in the walls and into the furnace.

SELF-SUPPORTING AIR-COOLED REFRACTORY WALLS may be built entirely of standard size brick, or with special refractory tile in the furnace lining, bonded to the outer wall. Fig. 28 shows two forms of this type of wall. In each, the inner wall is flexibly bonded to the outer wall, to provide for differences in expansion. Sometimes larger blocks are used, instead of the standard brick, to reduce the number of inner wall joints.

Special forms of air-cooled blocks sometimes are used in the clinker belt, as shown in

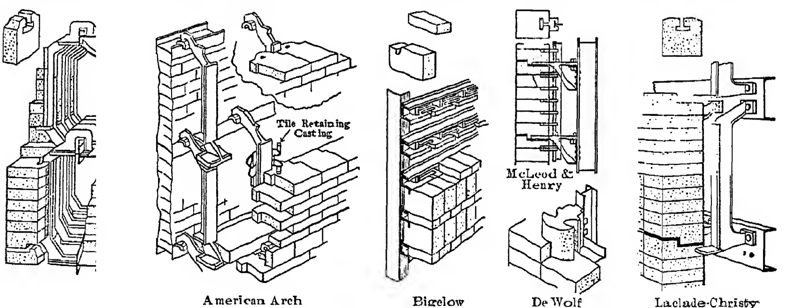

FIG. 29. Sectional Self-supporting Air-cooled Refractory Walls

Fig. 11, and sometimes for lining the entire wall. Some blocks have openings that permit flow of air through the block and into the furnace in order to cool the surface next to the fire, thereby reducing adherence of clinker.

Self-supported hollow walls cannot be used in extremely high furnaces because of the inability of the lower part of the walls, when hot, to carry the load of the upper part.

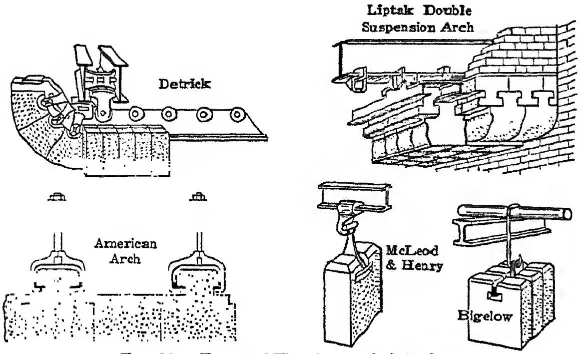

Fig. 30. Types of Flat Suspended Arches

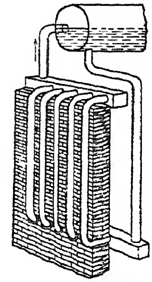

Fig. 31. Typical Arrangement of Bare-tube Furnace Wall

SECTIONALLY-SUPPORTED AIR-COOLED REFRACTORY WALLS usually are built in horizontal belts 2 to 3 ft. high, attached to an outside steel structure. Static load on the brickwork thus is reduced and a means provided to support the wall when refractory replacements are made. Fig. 29 shows typical forms. Different makes vary in shape of the refractories, number of special shapes, brackets and type of supporting steel, methods of providing for expansion and for sealing joints.

ARCHES over the fuel beds are seldom curved or sprung. Flat suspended arches (see Fig. 30) are more desirable. They require less skill in erection, exert no end thrusts, do not distort when heated, and if necessary can be repaired while the furnace is in operation. The refractory tile are air-cooled on the back side, flexibly supported, can expand or contract freely, and have no additional weight to support. One make, not shown, incorporates a veneer of silicon carbide, enabling the arch to withstand very high temperatures, rapid temperature changes and slagging action.

Properties desired in a good refractory are relative infusibility, relatively low thermal conductivity, flexibility of structure, low thermal expansion, impermeability toward gases and liquids, chemical inertness, and resistance to abrasion. See Refractories in Vol. 3 of this series. Failure of a refractory in a boiler furnace may be due to one or more of the following: Fusion; subsidence under load; spalling; slag action; changes in dimension.

Water-cooled Furnace Wall

WATER-COOLED METAL FURNACE WALLS are of three types: Bare-plate, bare-tube and covered-tube walls. They are more costly than refractory walls, but can withstand more severe conditions. In general, they are used only in locations where the refractory wall would deteriorate rapidly, for instance in the bridge wall of underfeed stoker furnaces, or that part of the side wall immediately adjacent to the fuel bed of traveling-grate stokers operating at moderate rates. If higher rates of combustion are maintained with either type of stoker, the entire wall surface and arches may require water cooling.

Bare-plate Wall furnaces are those in all internally fired boilers, as Scotch marine boilers, locomotive boilers, etc.

Bare-tube Walls are connected into the boiler circulation system, as in Fig. 31. They may be constructed of plain tubes (Fig. 32) or fin tubes (Fig. 33). In some arrangements, the water walls form a separate boiler that discharges its steam into an upper drum of the main boiler. The plain tube walls usually comprise tubes fairly closely spaced, connected to external headers and backed with firebrick walls. Other arrangements stagger the tubes in two rows or use special bifurcated tubes; the space between tubes then is but 1/4 in., forming a practically continuous water wall. In Fig. 32*a*, the back sides of the tubes receive heat by radiation from the firebrick backing, if the space between tubes does

not fill with sintered fly ash or molten slag. Arrangements b, c, d, Fig. 32 often are used in gas- or oil-fired furnaces. The tube is embedded to half its depth in plastic refractory or tile. The enclosure of the furnace wall in sheet metal and insulation permits reduction of the refractory to 9 in. thickness. In Fig. 32e, machined cast-iron blocks, clamped to the tube by welded studs, protect the refractory backing and increase heat transmission to the tubes.

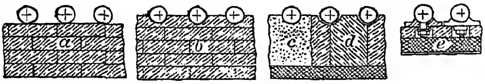

Fig. 32. Arrangement of Wall Behind Tubes

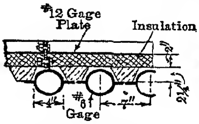

Fig. 33. Fin-tube Water Wall

Fig. 34. Drake Integral Block Water Wall

In the fin-tube construction, Fig. 33, the longitudinal fins are welded to each tube at opposite ends of a diameter. If the fins are too wide, the edges will burn back. If they are too long, they will warp and tear away from the tubes. Insulation behind the tubes, when used instead of refractory, is supported on lugs welded to the tubes.

COVERED-TUBE WALLS usually consist of tubes protected either by integral blocks or attached blocks; the latter may be all metal, all refractory, or metal coated with refractory. The blocks generally are rectangular, with flat faces, and form a substantially continuous flat surface when placed close together.

Integral Block construction is obtained by casting iron blocks on boiler tubes. See Fig. 34. Thermal contact between block and tube is good. Space must be left between blocks to permit growth of the cast iron. A close approximation to the good thermal contact of this construction is obtained by shrinking internally-machined cast-iron blocks on accurately-sized tubes. See Fig. 35.

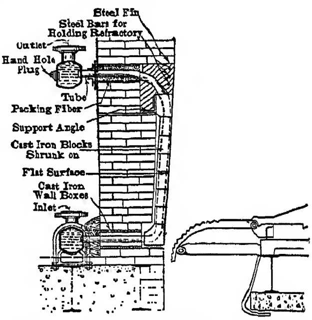

Fig. 35. Foster-Wheeler Shrunk Block Water Wall

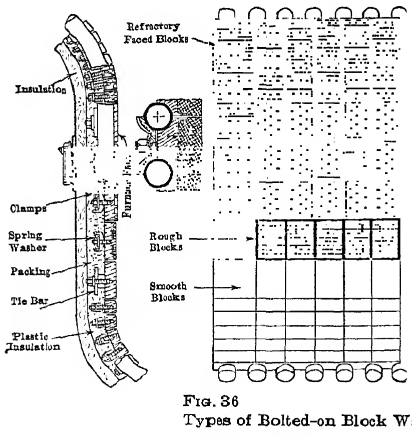
Attached Block construction comprises metallic blocks bolted to the water-wall tubes. Various types are shown in Figs. 36, 37 and 38. With such construction, furnace temperatures are higher than with bare-tube walls under identical conditions, because of the lower heat transmission of the block-tube walls. This may be important at light loads.

Either cast iron or steel may be used for the blocks shown in Fig. 36. Depending on



. 37

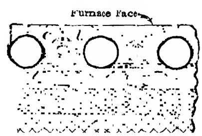


Fig. 36 . 38

Types of Bolted-on Block Water Walls

furnace conditions, the face exposed to the fire may be bare or coated with refractory; the bare face may be plain or ribbed. Refractory-faced blocks are used where high-tempera-

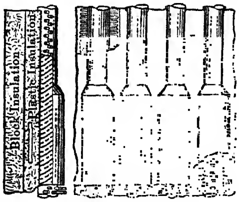

FIG. 39

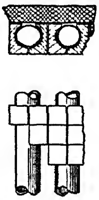

FIG. 40

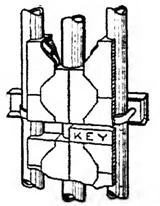

FIG. 41

Types of Refractory-protected Water-tube Walls

ture walls are necessary to assist combustion, and bare blocks where cooling surface is desirable. The blocks span the space between the tubes to which they are attached, and make good thermal contact by reason of ground joints and a plastic filler.

In Fig. 37, embossed sheets of a special alloy, which decreases the thermal resistance, are interposed between the cast-iron blocks and the tubes. In Fig. 38, the bare or refractory-faced blocks and tubes are brought in close contact by channels and toggle joints.

Refractory-protected Water Tubes are shown in Figs. 39, 40, and 41. Walls of this type usually transmit heat less rapidly than do walls of all-metal blocks. Refractory-protected water-tube walls materially assist in maintaining high furnace temperatures at low fuel-burning rates. In the stud-wall construction, Fig. 39, short iron studs are welded on the tube surface where plastic refractory is to be installed. The entire wall-tube surface in the hot parts of a furnace can be completely covered with a thickness of plastic refractory that will give the desired rate of heat absorption, while tubes in the cooler parts of the wall can be bare except for the refractory-covered studs between tubes. The studs support the refractory and cool it by providing a good heat conductor to the water in the tubes. In Fig. 40, small fireclay blocks are slipped around ordinary boiler tubes. The rate of heat transfer to the tubes can be increased by using silicon-carbide blocks. Such walls may be backed with refractories, block insulation, or a combination of both. The outer surface of the wall should be coated with a sealing cement or steel casing to prevent infiltration of air. In Fig. 41, interlocking fireclay, silicon carbide or cast-iron blocks maintain intimate contact with the tubes without the use of clamping devices. Horizontal structural-steel channels so support belts of the blocks that by the removal of key blocks, any block can be removed without disturbing any of those above it.

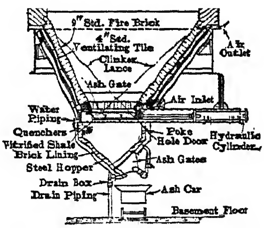

FIG. 42. Ash Hopper for Stoker-fired Furance

Furnace Bottoms

The type of furnace bottom used depends on the fuel, characteristics and methods of removal of the ash, method of firing, initial cost and maintenance costs. Hand-fired or stoker-fired furnaces, operated at moderate rates, usually have ashpits, cleaned by hand. See Fig. 4.

Stoker-fired furnaces, operating at higher rates, have ash hoppers of large capacity, The steel hopper is lined with second-grade, hard-burned firebrick, paving brick, or cast-iron air-cooled plates. The hot ashes usually are quenched by water sprays. In some installations, the ashes are carried away by hydraulic sluices. See Section on Material Handling, Vol. 3 of this series.

Oil- or gas-fired furnaces have solid bottoms, or bottoms with air-cooled passages. Air-cooled bottoms may be of refractory hollow tile, or of several layers of flat interlocking tile carried on standard brick on edge, but not in contact with each other.

Pulverized-coal-fired furnaces have either dry or wet bottoms.

Dry Bottoms are the more common. In them, the ash deposited on the bottom is solidified. To prevent the deposited ash from forming into large clinkers, the design must incorporate water screens of 4-in. tubes on 14-in. centers, above the furnace floor, air-cooled furnace bottoms, combinations of these two, or water-cooled bottoms.

Wet Bottoms, used in slag-tap or slagging boiler furnaces, form a hearth in which the molten ash collects in a pool. It remains molten and is tapped off either continuously or periodically, similar to the tapping of a foundry cupola. The molten ash, as it flows out, is granulated by a high-velocity water jet driving it against a plate, or by falling through a spray of multiple water jets. Wet-bottom furnaces originally were built to handle ash of fusion temperatures of 1900 to 2000° F., but inasmuch as the flat incandescent furnace bottom aids combustion, an additional advantage accrues from the saving in space requirements. As a result, furnaces have been developed to burn coals with ash fusion temperatures as high as 2600° F. In these furnaces, flames from the burners must bathe the hearth. Operation at high combustion rates only may be necessary, as the ash may solidify at low rates. Fluidity of the ash can be increased by adding limestone or other flux. See P. Nicholls and W. T. Reid, Fluxing of Ashes and Slags as Related to the Slagging Type of Furnace, *Trans.* A.S.M.E., RP-54-9, 1932.

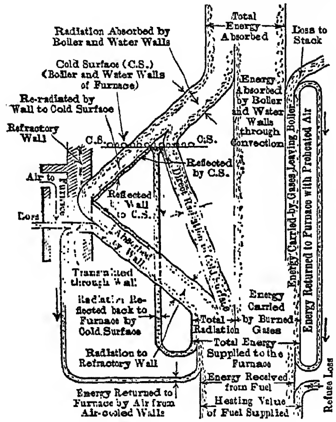

Fig. 43. Heat-flow Diagram of Boiler Furnaces

Preheated air can be used to full advantage to aid combustion of pulverized coal in wet-bottom furnaces without the troubles of ash-removal from the furnace bottom that occur in dry-bottom furnaces.

A type of all-refractory wet bottom, usually installed in furnaces with water-cooled walls, is built on steel plates carried on an air-cooled structure of piers and I-beams. Three or four courses of $2\,{}^1/_2$-in. firebrick are laid on the plates, and covered with $7\,{}^1/_2$ to 9 in. of burned dolomite or plastic chrome refractory. Extra courses of firebrick, laid near the furnace walls, form a saucer-shaped bottom. The tap-hole at the side of the furnace, is plugged by a ball of fireclay.

Furnaces with all-refractory wet bottoms are fairly satisfactory only when used with coals of low ash-fusion temperatures, at uniform, high combustion rates. Whenever the bottom cools, cracks may develop which will fill with slag. With frequent cooling the size of the bottom continually increases, ruining the seal at the furnace walls and displacing the water-cooled side walls. Iron sulphide, formed from iron pyrites in the coal, has a particularly bad erosive effect on the refractory, especially in cracks. The amount of iron sulphide formed can be reduced by pulverizing the coal until 80 to 90% passes through a 200-mesh sieve, as compared with the usual 65 to 70%.

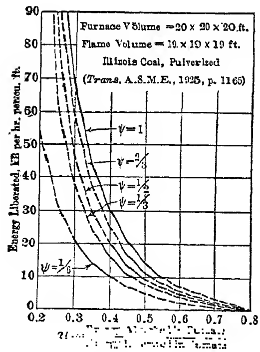

Fig. 44. Relation of ψ and Energy Release Rate (kB = 1000 B.t.u.)

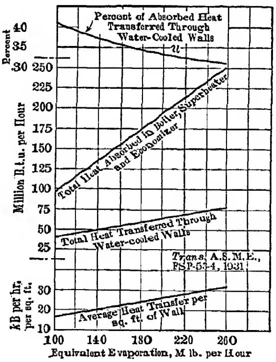

Fig. 45. Typical Heat Transfer Relations in Pulverized Coal Furnace

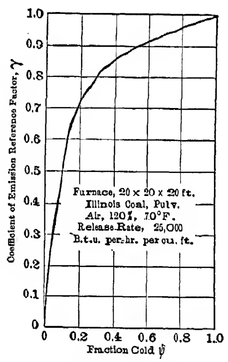

Fig. 46. Typical Relations of ψ and γ

The most satisfactory wet bottoms up to 1936 have been built of smooth cast-iron blocks (Fig. 36) on water tubes connected into the boiler circulation system. R. Shellenberger describes (Furnace Bottoms for Tapping Ash in the Molten States, *Mech. Engg.*, Jan., 1936) a construction that provides horizontal buck stays capable of exerting a pressure of several thousand pounds per foot of wall between the furnace bottom and the water-cooled side walls to insure tightness against leaks. Bottom-supported walls thus may be held constantly in contact with the bottom and can expand and contract on rollers as the unit is put into and out of service. The furnace may be designed for either periodical or continuous tapping of the slag. Tapping-spout maintenance is reduced by water cooling. Continuous tapping requires a fairly large tap hole, centrally located in the furnace bottom, kept free and open by withdrawing through it some of the hot furnace gases.

8. ENERGY INPUT AND OUTPUT OF A BOILER FURNACE

The heat energy input and output of a boiler furnace having a combination of air-cooled and water-cooled walls may be shown by a heat-flow diagram. See Fig. 43. Energy supplied to the furnace is distributed to the boiler, to the exit flue gases, and to the furnace walls. The latter is by radiation from solid masses of fuel and slag, by radiation from gases and fly-ash, and by convection. The temperature of the furnace-face of the wall at any point depends on the temperatures, relative area and location of the other surfaces in the furnace, as part of the heat received by any part of the furnace wall is radiated and reflected to colder surfaces " seen " by it.

FRACTION COLD. All water-cooled surfaces in a furnace, *i.e.*, walls and slag screens plus that part of the boiler surface receiving radiation, is considered collectively as *Cold Surface.* The ratio (actual cold surface ÷ maximum possible cold surface) is defined as the *Fraction Cold* (ψ). The value of ψ has an important bearing on furnace temperature. Cold surface can be used instead of refractory surface in all or part of the furnace walls to limit furnace temperature, at maximum combustion rates, to a value at which fly-ash will not damage the refractories. If the substitution is carried too far, furnace temperature at low combustion rates may be too low for good combustion. The proportion of energy released in a boiler furnace varies with the value ψ as shown, in a general way, in Fig. 44.

Fig. 45 shows, for a particular pulverized-coal-fired furnace, with $\psi = 1$, the effects of load variation on total energy release, on the relative amount of energy absorbed by water walls, and on the rate of heat transfer per unit of surface.

In a proposed steam-generating unit, the total heat release rate necessary in the furnace to carry the load may be calculated, and an apparently satisfactory specific heat-release rate selected for the desired furnace wall construction and operating conditions. From these figures, the tentative dimensions of the furnace can be determined. These are modified to give the final design, after investigation of furnace and wall temperatures, and heat transmission rates to and from the walls.

In calculating probable heat transfer to the furnace walls, only that transferred by radiation need be considered, as the total transfer by conduction and by convection is approximately only 6 or 7%. The rate at which the walls will receive heat by radiation can be computed by the method given in Heat Power Engineering, by Barnard, Ellenwood, and Hirshfeld (John Wiley & Sons), Part II, chap. xxvi.

For combined refractory and water-cooled furnace walls, the proportion of total heat released in the furnace that is transmitted to the walls is intermediate between that transmitted to all-refactory walls or all-water-cooled walls. Heat is interchanged between the refractory and the water-cooled surfaces. The analytical methods of calculation are complicated, but Wohlenberg and Lindseth (The Influence of Radiation in Coal-Fired Furnaces on Boiler-Surface Requirements, and a Simplified Method for Its Calculation, *Trans.* A.S.M.E. xlviii, p. 849, 1926) have presented a simpler method, using charts which show the influence of the fraction cold. The fraction u_c of furnace energy liberated, that would be absorbed by the walls of a completely water-cooled furnace ($\psi = 1$) equal in size to the furnace being analyzed, first is determined. This may be estimated from a chart similar to Fig. 44. Then u = the fraction absorbed by the water walls of the actual furnace being considered, $= u_c \times \gamma$, where γ = a suitable factor based on the actual fraction cold. γ is the coefficient of emission reference factor, and is defined as

$$\gamma = \frac{\text{energy absorbed by water walls in given furnace cavity}}{\text{energy absorbed in same cavity with } \psi = 1}$$

Typical relations between γ and ψ are given in Fig. 46.

For any set of conditions, a certain value of ψ will require, for a given final gas temperature, the minimum total surface in furnace and boiler, which value is the most effective fraction cold for the stated conditions.

Heat Transmission Through Furnace Walls

The rate of heat transmission through furnace walls depends on the character of the materials in the wall, the location of the various elements of the wall relative to each other, and the method of cooling.

As the heat is transmitted by conduction, rate of transmission depends on the thermal conductivity of the materials used, and varies inversely with thickness. Many furnaces are built with insulation behind a 9-in. firebrick lining, instead of with the former 18- to 22 1/2-in. firebrick walls. The effect of insulation in the wall is to flatten the temperature gradient through the firebrick lining. See Fig. 47. This may be beneficial to the firebrick, but excessive thickness of insulation together with high furnace temperatures may cause softening or incipient fusion of the lining, and promote slag action. Table 7 and Fig. 48 show heat losses through various types of solid walls.

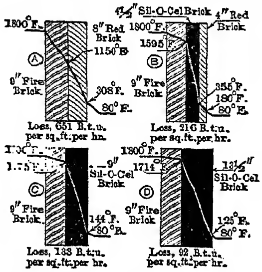

Fig. 47. Variation of Temperature Gradient and Heat Loss in Furnace Walls

So-called dead-air spaces should not be used between inner and outer walls of furnaces. A considerable amount of heat would be radiated across them, and the air would carry heat from one wall to the other by convection. If double-wall construction must be used, the space should be filled with granular material as sand or ashes.

AIR-COOLED WALLS.—Forced cooling of refractory walls by passing air through ducts in the walls is a complex process of heat transmission. Figs. 49 and 50 show thermal relations existing in two typical installations. The decrease in rate of heat transmission along the duct has little significance, and only one average rate for the entire length usually is considered. For the installation represented by Fig. 49, average heat transmission is about 2600 B.t.u. per hr. per sq. ft. of wall surface; the overall coefficient of heat transfer from the hot surface of the lining to the air is 1.01 B.t.u. per hr. per sq. ft. per deg. F. temperature difference. This value of overall coefficient is representative for all the common examples of air cooling through fireclay brick linings. In the installation represented by Fig. 53, the average overall coefficient was 6.3.

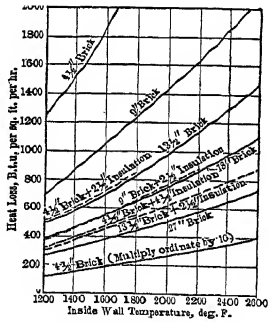

Fig. 48. Heat Loss through Furnace Walls, with Atmospheric Pressure in Furnace

WATER-COOLED WALLS.—The difference in temperature between the hot surface and the water in the tubes depends on the temperature of the furnace gases and surrounding bodies, the heat absorbing and transmitting power of the various elements making up the wall, and the temperature of the inner surface. This last depends on the rate at which the water in the tube

† Insulation *A* is natural Sil-O-Cel, for temperatures up to 1600 deg. F. Insulation *B* is Sil-O-Cel C-22 for temperatures up to 2000 deg. F. Insulation *C* is Sil-O-Cel "Super," for temperatures up to 2500 deg. F.

removes the heat transmitted through the wall. Temperatures must not be permitted to rise to a point that will cause failure of any portion of the wall.

The temperature gradients through wall-protecting blocks, as shown in Fig. 36, and the corresponding heat-transmission rates encountered in actual service are shown in Fig. 51. Fig. 52 shows probable relative heat-absorption rates of several kinds of water-walls, of another make. The safe rate of heat absorption by bare water-wall tubes (4 in. O.D., No. 8 gage) is 85,000 B.t.u. per hr. per sq. ft. of projected area exposed to radiation.

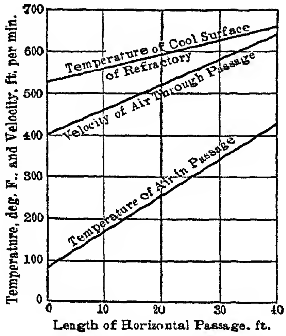

Fig. 49. Thermal Relations in a 9-in. Fireclay Air-cooled Refractory Wall. Initial Air Velocity, 400 ft. per min.

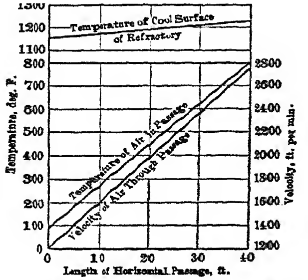

Initial air temp., 90° F.; temp. of hot surface of refractory, 2800° F.; passage 9 in. wide, 24 in. high.

Fig. 50. Thermal Relations in a 9-in. Silicon Carbon Air-cooled Refractory Wall. Initial Air Velocity, 1200 ft. per min.

The heat transmission rate through the stud-tube water walls (Fig. 39) is approximately equal to that of construction BAG, Fig. 51, if the length of stud on the front face of the tube is 1 in. and if the refractory is flush with the end of the stud, which is standard construction. For partially-studded walls, with studs and refractory between 3 1/2-in. tubes on 6 in. centers, the resulting surface is about 50% bare tube and 50% covered tube. For the refractory-covered portion between the tubes of such walls, the heat transmission rate is about 65% greater than the mean value for the full stud wall.

The heat-absorption rate of fin-tube water-cooled walls, Fig. 33, probably is no greater than that of ordinary tubes backed by refractory walls, if both walls are clean. In the latter case the refractory walls radiate and reflect heat to the back sides of the tubes. The fin-tube wall has the advantage in actual service, as the refractory wall between and behind the standard tubes usually is coated with slag and ash, which may build out over a portion of the front side of the tubes, partially shielding them from radiant heat.

Influence of Different Variables

Many individuals have investigated the influence of various factors on design and operation of boiler furnaces. For a comprehensive bibliography of 60 articles, see An Experimental Investigation of Heat Absorption in Boiler Furnaces by Wohlenberg, Mullikin, Armacost, and Gordon, *Trans.* A.S.M.E., RP-57-4, 1935.

EFFECT OF FRACTION COLD AND HEAT-RELEASE RATE.—In Some Fundamental Considerations in the Design of Boiler Furnaces, by Wohlenberg and Brooks (*Trans.* A.S.M.E., FSP-50-39, 1928) the analyses assume the use of Illinois bituminous coal of 12,800 B.t.u. per lb. heating value, and ash fusion temperature, 2000° F., and of a certain specified ultimate analysis. The outstanding features of the results are shown in Figs. 53 to 58, in which fraction cold is represented by ψ, heat-release rate in B.t.u. per hr. per cu. ft. by R, radiation mean temperature of the gases in the furnace by t_U, mean temperature of the refractory walls by t_R, and the ratio of heat added by the furnace walls to the heat released in the furnace by u. Figs. 55 and 56 show that the permissible rate of heat release R may be increased as the fraction cold is increased.

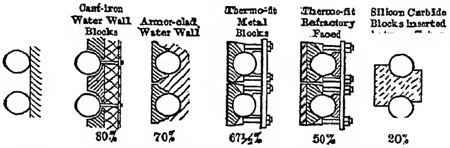

FIG. 52. Heat Absorption Rates of Water-cooled Furnace Walls

For powdered-coal firing, Fig. 60 shows that with a given flame temperature, t_U, higher heat release rates R, or smaller fraction cold, ψ, can be adopted in furnace design if excess air is increased, but with a decrease in efficiency. In operating a given unit, an increase of excess air permits heat release rates to be increased without exceeding limiting gas temperature. Wall temperatures indicated in Figs. 53–54 are mean temperatures that may be expected. Actually, local hot spots may be 300 to 400° F. higher. These locations must have greater cooling and fraction cold. Otherwise, the materials would attain temperatures above that at which they can survive.

Figs. 53 and 54 are approximately correct for a furnace volume of 27,000 cu. ft. when using West Virginia coal with a heating value of 14,500 B.t.u. per lb. and ash fusion temperature of 2500° F., except that the values of u would be a little higher than those of the curves, which are for a volume of 8000 cu. ft. Other results show that if the air temperature is 500° F., t_U and t_R increase not over 150° F., and u is raised about 0.08.

EFFECT OF CHARACTER OF COAL.—Wohlenberg and Anthony (Influence of Coal Type on Radiation in Boiler Furnaces, *Trans.* A.S.M.E., FSP-51-36, 1929) found

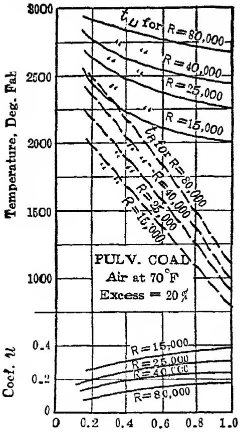

FIG. 53

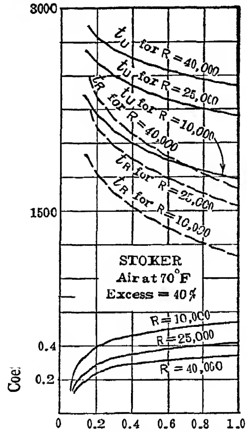

FIG. 54

Effect of Fraction Cold ψ and Heat Release Rate R on Furnace Conditions

t_U = Radiation mean temperature of gases in furnace, deg. F. t_R = Mean temperature of inner surface of refractory, deg. F. u = Energy absorbed by furnace walls ÷ energy released

the heating value of the coal to be the most significant index of the influence of type of coal on flame temperature. The investigation covered furnaces having various values of fraction cold and heat release rates. Based on the assumption that different kinds of coal were burned in pulverized form with 20% excess air at 500° F.,

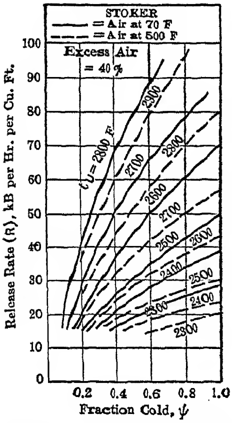

FIG. 56. Effect of Fraction Cold ψ and Heat Release Rate on Furnace Flame Temperature

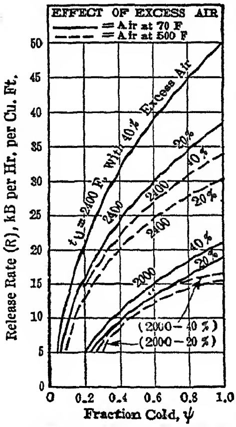

FIG. 57. Effect of Excess Air, Powdered Coal Firing t_U = furnace gas temperature, deg. F.

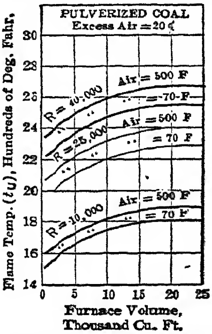

FIG. 58. Effect of Increased Furnace Volume (ψ = 1)

it was indicated that a heat absorption rate of about 160,000 B.t.u. per hr. per sq. ft. of projected area of bare iron water-cooled surfaces changes about 6000 B.t.u. with each 1000 B.t.u. per lb. change in heating value of the coal, heat release rate being maintained constant; when the heat-absorption rate is about 20,000 B.t.u. its change is negligible with variations in heating value of the coal. Further conclusions were that, with coal of a heating-value of 10,000 B.t.u. per lb. and flame temperature of about 3000° F., each 1000 B.t.u. per lb. change in heating value of the coal changes flame temperature about 50° F., heat release rate remaining unchanged; when flame temperature is around 2500° F., the change is about 25° F. The rate of change in flame temperature with variations in heating value decreases from the above figures with increases in heating value of coal above 10,000 B.t.u. per lb., and increases with decreases in heating value.

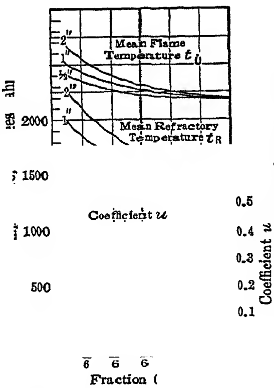

FIG. 59. Relations of Flame Temperature, Refractory Temperature, Refractory Thickness, ψ and u. Heat Release Rate, 25,000 B.t.u. per hr. per sq. ft. per deg. F.

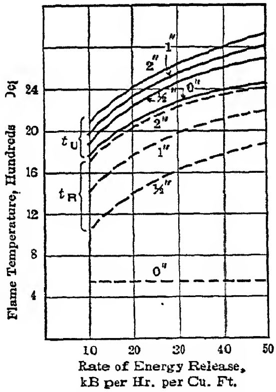

FIG. 60. Relation of Refractory Thickness and Energy Release Rate in Furnace where ψ = ½

EFFECT OF FURNACE VOLUME.—The effect of furnace volume with respect to flame temperature when burning pulverized coal in a completely water-cooled furnace, is shown in Fig. 58. A similar effect is shown on refractory-wall temperatures. Fig. 57 shows that, with pulverized coal, increasing furnace volume has a decreasing effect on flame temperature with larger furnaces. Changes in volume of stoker-fired furnaces affect these temperatures but little.

REFRACTORY FACINGS on water-cooled wall surfaces improve combustion conditions, especially at lower fuel-burning rates. Larger furnaces are required for the same steam output. Refractory-faced water-cooled walls permit higher furnace temperatures and greater heat-release rates than solid refractory walls.

Wohlenberg and Brooks have shown (*Trans.* A.S.M.E., FSP–50–39, 1928) that water cooling results in but small thermal advantage with flat water-cooled walls if the refractory face is over 2 in. thick, intimately bonded to the metal wall. Conductivity of refractory assumed at 10 B.t.u. per hr. per deg. F. per sq. ft. Fig. 59 shows the variation, with fraction cold, ψ, and thickness of refractory, of flame temperature, of temperature of inner surface of refractory and of ratio u (= heat absorbed by furnace wall ÷ heat released in furnace). Conditions given are as follows: Coal, West Virginia or Illinois; furnace, 20 × 20 × 20 ft.; air, 70° F., 20% excess; refractory, maximum thickness, 2 in., conductivity k, 10 B.t.u. per hr. per deg. F. per sq. ft. (for any other conductivity, multiply thickness in Fig. 59 by 0.1 k). Fig. 60 shows the relation between flame temperature t_U and refractory temperature t_R when heat release rate and refractory thickness are varied, furnace conditions being as above. Change of entering air temperature from 70° to 500° F. will have the following effects: t_U increases about 50° F.; t_R increases about 25° F. with refractory thickness of $1/2$ in., and about 100° F. with 2 in. thickness. Increasing thickness of refractory facing requires larger furnace volume for maintenance of the same flame temperature. Thus, for a given furnace temperature, heat release rates in B.t.u. per hr. per cu. ft. would be as follows: Bare water walls, 30,000; $1/2$-in. facing, 23,000; 2-in. facing, 16,000. Relative furnace volume would be inversely as the heat release rates.

Wall temperatures indicated in Figs. 53–54 are mean temperatures that may be expected. Actually, local hot spots may be 300 to 400° F. higher. These locations must have greater cooling and fraction cold. Otherwise, the materials would attain temperatures above that at which they can survive.

Manufacturers of representative air-cooled and water-cooled furnace walls are: *Air-cooled Walls:* American Arch Co., New York; Bernitz Furnace Appliance Co., Boston; Bigelow-Liptak Corp., Detroit; M. H. Detrick Co., Chicago; DeWolf Furnace Corp., Rochester, N. Y. *Water-cooled Walls:* American Engineering Co., Philadelphia; Babcock & Wilcox Co., New York; Combustion Engineering Co., Inc., New York; Riley Stoker Corp., Worcester, Mass.; Superheater Co., New York.

CHIMNEYS AND DRAFT*

1. NATURAL DRAFT

STATIC DRAFT.—The height and diameter of a properly-designed chimney depend primarily on type and amount of fuel burned, temperature of flue gases, summation of resistances in the apparatus and connections, and altitude of plant above sea level. As yet no formulas have been evolved to take all factors into consideration, and existing formulas are largely empirical.

Flow of gases through a chimney is produced by the difference in weight between the column of hot gases in the chimney and a column of equal height of outside air. Draft is the difference in pressures exerted by the two columns, and is measured by the weight per unit area. The difference of pressure usually is expressed in inches of water. The intensity, for a given gas and air temperature, varies with the height of the comparative columns, and therefore, height of chimney is a prime factor in producing the required intensity of draft. The intensity of the draft is

$$D = 0.52\,PH\{(1/T) - (1/T_1)\} \;.\;.\;.\;.\; [1]; \qquad D = KH \;.\;.\;.\;.\; [2]$$

where D = draft produced, in. of water; P = atmospheric pressure, lb. per sq. in.; H = height of stack above breeching entrance, ft.; T = atmospheric temperature, deg. F., abs.; T_1 = temperature of stack gases, deg. F., abs.; K = a factor, depending on temperature of stack gases (see Table 1). Density of flue gases is assumed to be the same as that of air. This assumption introduces, for usual fuels and operating conditions, an error of less than 1.5%.

Temperature T_1 should be considered as the effective mean temperature in the stack. It is likely to be lower than that of the gases leaving the boiler setting, as it is affected by air infiltration at leaky joints in flues or stack connections, and also by heat losses from the flues and the stack itself. Considerable doubt exists as to dependable methods for

Table 1.—Values of K at Atmospheric Pressure, 14.7 lb. per sq. in.

K at 80° F.	0.0078	.0076	.0073	.0070	.0066	.0062	.0057	.0053	.0048

* Staff revision.

determining effective mean temperature in the stack, but for nominally tight connections, it is justifiable to use boiler outlet gas temperature, reduced 20° to 50° as a margin of safety, as a basis for calculating the chimney height for power or industrial process boilers. For domestic boilers see p. 11–11.

The effective mean temperature of the gases in the chimney, according to Cotton, is $C(T_b - T_a) + T_a$, where T_a, T_b = respectively, atmospheric air and boiler exit gas temperatures, deg. F., and C = factor from Table 2. Smallwood (*Mech. Engg.*, Jan. 1933) believes that the factors of Table 2 are low, and that actual average temperatures in the stack are very nearly equal to entering gas temperature, provided there is no air infiltration.

AVAILABLE DRAFT. LOSS DUE TO FRICTION AND INERTIA.—The intensity of draft by formula [1] is static, and never is observed with a draft gage or recorder. It does not obtain after the gases begin to flow. When boiler is in operation, *available draft* is the difference between static draft (formula [1]), and the amount lost in overcoming inertia and frictional resistance within the chimney proper, or draft indicated by a draft gage connected to the base measuring point of the stack. Loss of draft due to friction is

. . . . [3]

d = draft loss, in. of water; W = weight of gas, lb. per sec.; M = average perimeter inside of stack, ft.; H = height of stack, ft.; A = average area inside of stack, sq. ft.; f = friction coefficient. Approximate values of f are: 0.0008 for steel stacks, temperature of gases, 600° F. (0.0006 at 350°); 0.00105 for brick or brick-lined stacks, tempera-

Table 2.—Factors for Effective Mean Temperatures of Gases in Chimney.*

Calculated from Fig. 5 in Determination of Chimney Sizes, *Mech. Engg.*, Sept., 1923

Height of Chimney, ft.	Chimney Diameter, ft.					
	6	10	14	18	22	26
	Factor C					
100	0.86	0.875	0.89	0.91	0.93	0.95
200	.775	.80	.825	.85	.88	.91
300	.74	.775	.80	.83	.87	.90
400	.725	.76	.79	.825	.865	.895

* Brick Chimney. These factors may be greatly modified if the chimney is not air tight.

Table 3.—Available Draft for 100-ft. Steel Stacks

Based on atmospheric temperature of 80° F., stack temperature of 500° F. and 2 lb. of gas per lb. of steam from and at 212° F. at sea level. For other heights of stack, H, multiply draft by $H/100$*.

Steam per Hour, lb.	Diameter of Stack, Inches																		
	36	42	48	54	60	66	72	78	84	90	96	102	108	120	132	144	156	168	180
	Available Draft, Inches of Water																		
5,000	0.60	0.61	0.61	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....
10,000	.54	.58	.60	0.61	0.61	0.61	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....
